Prevalence of tic disorders peak during the late first decade and early second decades of life due to the clinical course of the disorder and are roughly one-third as prevalent in adulthood (Bloch and Leckman 2009; Bloch et al. 2006; Leckman et al. 1998). There is a male predominance of TS with boys about twice as likely to be affected by tic disorders as girls (Scahill et al. 2005).

Natural History, Prognostic Factors, and Outcomes

The onset of TS is usually characterized by the appearance of simple, transient motor tics that affect the face (typically eye blinking) around the age of 5–7 (Leckman et al. 1998). Over time, these simple motor tics generally progress in a rostrocaudal direction affecting other areas of the face, followed by the head, neck, arms, and, lastly and less frequently, the lower extremities. With time, vocal tics often appear, tics become increasingly complex, and premonitory urges appear. Premonitory urges are feelings of tightness, tension, or itching that are accompanied by a mounting sense of discomfort or anxiety that can be relieved only by the performance of a tic (Leckman et al. 1993). With increasing awareness of premonitory urges, TS patients begin to exhibit a variable degree of voluntary control over tic performance. However, this voluntary control should be likened to that governing control of eye blinking. Eye blinking and tics can both be inhibited voluntarily, but only for a limited period of time and only with mounting discomfort. Thus, some adult TS patients are able to demonstrate nearly complete control over when expression of their tics will occur. However, when complete or

near complete control of tics is present, resistance to the mounting tension of premonitory urges can produce mental and physical exhaustion even more impairing and distracting than the tics themselves.

The severity of tics in TS waxes and wanes throughout the course of the disorder (Peterson and Leckman 1998). Tics are highly variable from minute to minute, hour to hour, day to day, week to week, and month to month. Tic episodes occur in bouts, which in turn also tend to cluster. Tic symptoms, however, can be exacerbated by stress, fatigue, extremes of temperature, and external stimuli (i.e., in echolalia tics). Intentional movements attenuate tic occurrence over the affected area, and intense involvement and concentration in activities tends to dissipate tic symptoms.

TS symptoms generally peak in severity between the ages of ten and twelve. Tic severity typically begins to decrease with the onset of adolescence (Bloch et al. 2006; Leckman et al. 1998). Reduction in tic severity generally ends by the early twenties. Although a small minority of TS patients does experience catastrophic outcomes in adulthood, on the whole, individuals rarely experience either a sustained worsening or improvement of their symptoms after their mid-20s. One-half to two-thirds of individuals with TS experience a marked reduction of symptoms by their late teens and early twenties, with one-third to one-half of these patients becoming virtually asymptomatic in adulthood.

Evaluation and Differential Diagnosis

A diagnosis of Tourette syndrome or chronic tic disorders is made through clinical history and observation. A childhood onset, the waxing-and-waning severity, and changing nature of tic symptoms are critical in establishing the diagnosis. In older children, the presence of premonitory urges and the exacerbation of tics in response to stress and fatigue are also helpful clues in establishing the diagnosis. In children, tics often need to be distinguished from stereotypies of stereotyped movement disorders or pervasive developmental disorders. Stereotypies typically have an earlier

age of onset than tics, are bilateral rather than unilateral, and have a soothing quality. Table 1 contrasts the attributes of tics and stereotypies. Complex tics often also need to be distinguished from compulsions of obsessive-compulsive disorder. Making this particularly difficult is the high comorbidity between the two conditions. Compulsions are usually performed in response to an obsession and preceded by anxiety, worry, or concern, whereas tics are generally performed in response to a physical sensation or premonitory urges. Compulsions typically are more elaborate than tics and are more likely to resemble “normal” behavior. Often, both a diagnosis of OCD and a tic disorder are warranted in the same individual.

The tics, which are the most prominent feature of TS, are often neither the first nor the most impairing psychological disturbance TS patients endure. Thus, a thorough evaluation for common comorbid conditions is also critical (Scahill et al. 2006). In screening for comorbidities in TS, ADHD, OCD, disruptive behaviors, and pervasive developmental disorders are of principle importance. Children with TS have higher rates of OCD, ADHD, PDD, and disinhibited speech and behavior compared to the general population. In the natural course of comorbid psychiatric illness in TS, ADHD symptoms, when they occur typically, precede the onset of tic symptoms by a couple of years, whereas OC symptoms typically present around the age of 12–13 after tics have reached their peak severity (Bloch et al. 2006). Approximately half of children with Tourette syndrome experience comorbid ADHD and an even

greater proportion of children with tic disorders reaching clinical attention. Roughly one-third to one-half of Tourette syndrome patients will experience clinically significant OCD symptoms during the course of their lifetime.

Educating the patient, his family members, teachers, and peers is among the most important interventions available to the clinician. It should be undertaken for nearly all patients with tic disorders. Family psychoeducation should focus on:

1. The tics are not voluntary or meant to be intentionally provocative. They typically occur in “bouts” when tics will appear in rapid succession followed by a tic-free interval.
2. Premonitory urges – the physical sensations like an itch or before a sneeze that many patients experience prior to performing tics. TS is a sensorimotor disorder. There is also a momentary sense of relief that follows the completion of the tic.
3. Suppressibility of tics – many patients are able to suppress their tics over the short term, but often this is at the expense of increasing discomfort and distraction due to the premonitory urges. So it is not uncommon for a child to have relatively minor tics at school and then return home to let loose a bout of tics.
4. The natural waxing-and-waning course of tic symptoms – that there will be increases and decreases in tic severity over time. Due to the natural ebb and flow of symptoms in the illness, any interventions started during an

Tourette Syndrome, Table 1 Comparison between tics and stereotypies

	Tics	Stereotypies
Typical age of onset	4–8 Years	2–3 Years
Course of symptoms	Waxing and waning	Constant
Timing of movements	Brief and sudden	Continuous, rhythmic, and prolonged
Typical movements	Eye blinking, facial grimace, throat clearing	Arm flapping, rocking
Characteristics of movements	Typically unilateral	Often bilateral
Exacerbated by. . .	Stress, fatigue	Excitement
Premonitory urges	Present	Absent
Suppressibility	Often for short periods of time	Rare
Comorbid conditions	OCD, ADHD	PDD, autism spectrum disorders
Treatment	Neuroleptic, $\alpha 2$ agonists	No response to medication

exacerbation of tic severity may appear successful due to a natural decline in symptom severity.

5. The natural history of tic disorders – the illness tends not to be relentlessly progressive and symptoms usually improve by adulthood. This information often contradicts the impressions gained from the available lay literature on TS that typically focuses on the most extreme cases – which do typically occur in adulthood.
6. Exacerbating and alleviating factors – tics tend to be exacerbated by fatigue, sleeplessness, stress, excitement, and possibly changes in temperature and streptococcal infections. Tics often tend to be alleviated when a child is deeply engaged in a motor activity such as sports, playing musical instruments, and dancing. The exact exacerbating and alleviating factors are highly individualized to the patient. Healthy habits such as good sleep hygiene and regular exercise can only improve tic symptoms.
7. Education on comorbid ADHD, OCD, learning disabilities, and disruptive or disinhibited behaviors when present. Improving these disorders often leads to an improvement in the tics.
8. Provide resources to help educate parents and teachers about tic disorders. These are available at the Tourette Syndrome Association website: <http://www.tsa-usa.org> and <http://www.tourettesyndrome.net>.

Treatment

Given the waxing and waning course of tics and the decline in tic severity that usually occurs in adolescence, any intervention performed in response to symptom exacerbation will usually be followed by clinical improvement. The goal of treatment should be minimizing the level of social and educational impairment caused by tics rather than completely eliminating tics, which will be unsuccessful in the majority of cases. Many cases of TS can be successfully managed without medication. When coexisting conditions such as

ADHD, OCD, depression, or ODD are present, it is usually better to treat these “comorbid” conditions first, as successful treatment of these disorders often will diminish tic severity (Scahill et al. 2006).

Pharmacologic Interventions

Antipsychotic medications, dopamine D₂ receptor antagonists, are the most effective tic-suppressing medications (Scahill et al. 2006; Singer 2010). Among the typical antipsychotics, haloperidol and pimozide have the most studied and have the most convincing data demonstrating efficacy. Although antipsychotics have the greatest efficacy in treating tics, they are generally not recommended as first-line treatment because of poor tolerability. Common potential side effects include tardive dyskinesia, acute dystonic reactions, sedation, depression, school and social phobias, and/or weight gain. In many instances by starting at low doses and adjusting the dosage upward slowly, clinicians can avoid these side effects. The goal should be to use as little of these medications as possible to render the tics “tolerable.” Efforts to stop the tics completely often risk overmedication and increased side effects.

Due to the extrapyramidal side effects associated with typical antipsychotics, atypical antipsychotics, such as risperidone, olanzapine, and ziprasidone, are now the most widely used medications to treat tic symptoms. These agents have potent 5-HT₂ blocking effects as well as more modest blocking effects on dopamine D₂. There are currently double-blind clinical trials that have supported the efficacy of risperidone, olanzapine, and ziprasidone (Singer 2010). Atypical antipsychotics, especially olanzapine and risperidone, are associated with significant weight gain and sedation and increased risk of diabetes. Ziprasidone use can be associated with QT prolongation in children; so serial monitoring with electrocardiograms may be necessary. Due to the significant metabolic side effects associated with atypical antipsychotics, even though they are more effective at treating tics than other classes of medications, they are not recommended as a first-line intervention.

Clonidine and guanfacine are potent α_2 receptor agonists that are thought to reduce central noradrenergic activity. Although less effective in relieving tics compared to the antipsychotic medication, α_2 receptor agonists have the advantage of being better tolerated and also improving comorbid ADHD symptoms in patients with tics (Scahill et al. 2006; Singer 2010). The principal side effect associated with clonidine use is sedation which occurs in 10–20% of subjects and which usually abates with continued use. Other side effects include dry mouth, transient hypotension, and rare episodes of worsening behavior. Clonidine should be tapered and not withdrawn abruptly, to reduce the likelihood of symptom or blood pressure rebound. Guanfacine is generally preferred to clonidine because it is less sedating and not associated with rebound hypertension following withdrawal.

When comorbid ADHD is the most impairing illness in a patient presenting with comorbid tics, the stimulants methylphenidate and dextroamphetamine derivatives are still first-line agents for the medical management of ADHD. Although clinical trials of meta-analysis of psychostimulant use in children with ADHD and comorbid tics suggest that these medications do not worsen tic severity, there still exists an FDA warning against the use of psychostimulants in children with tic disorders or a family history of TS (Bloch et al. 2009). This FDA warning was exclusively based on data from clinical case reports and case series that reported worsening of tics when children were exposed to psychostimulants. For this reason, non-stimulant treatments are often used in the treatment of children with ADHD and comorbid tics. α_2 receptor agonists have the advantage of demonstrated efficacy for both ADHD and tic symptoms. Furthermore, the combination of clonidine and methylphenidate has been demonstrated to be more effective in treating ADHD symptoms in children with comorbid tics than either medication alone. Atomoxetine has also been demonstrated to be effective in the treatment of ADHD symptoms in children with comorbid tics and may also be modestly helpful in the treatment of tics.

Behavioral

Behavioral therapy has shown significant promise in the treatment of tic disorders. Behavioral therapy has been demonstrated to be significantly more effective than supportive therapy in reducing tic severity in children with TS in a large, randomized, multicenter trial using blinded raters (Piacentini et al. 2010). Behavioral therapy has also been shown to significantly reduce tic symptoms in adults with TS when compared to supportive therapy in randomized and unblinded trials (Deckersbach et al. 2005; Wilhelm et al. 2003). The measured effects of behavioral therapy in reducing tic severity have been similar to the most effective pharmacological agents used to treat tics.

Behavioral therapy for tics consists of two main components: (1) awareness training and (2) competing response practice (Woods 2001). Awareness training consists of 4 components designed to increase an individual's awareness of his own tics. These components include the following: (1) response description, in which the patient learns how to describe tic movements and reenacts them into a mirror; (2) response detection, in which the therapist aids the patient in tic detection by pointing out each tic immediately after it occurs in the session; (3) early warning procedure, in which an individual learns how to identify the earliest signs of tic occurrence; and (4) situational awareness training, in which an analysis is conducted to identify the high-risk situations where tics are most likely to occur. Competing response practice involves teaching individuals to produce an incompatible physical response (i.e., isometric contraction of tic-opposing muscles) contingent upon the urge to perform a tic.

Although behavioral therapy has significant evidence of efficacy and does not have the side effect burden of the medications used to treat tics, dissemination remains a significant barrier to the widespread implementation of this treatment for tics. Furthermore, the efficacy of behavioral therapy has not been demonstrated in special populations of children with tic disorders such as those with comorbid ADHD, pervasive developmental disorders, or intellectual disability.

Definition

Toxicology is the branch of science that studies the adverse effects of chemicals and environmental exposures on living organisms. It includes aspects of biology, chemistry, and medicine in the scientific approaches used. It studies the symptoms, mechanisms, measurement, and treatment of poisonous substances that people and other living things are exposed to.

The science of toxicology identifies chemical compounds and environmental events that

negatively impact health. It was initially considered as the study of poisons and has been expanded with the technological impact on the environment. The study of dose and effect is central to toxicology. Many compounds, such as lead, are toxic or harmful above certain levels of exposure. The risk for injury increases with the level of exposure. Toxicity refers to the biologic effect of a substrate or compound. The Society of Toxicology defines toxicology as “the study of the adverse effects of chemical, physical, or biologic agents on living organisms and the ecosystem, including the prevention and amelioration of such adverse effects.” Toxicologists are important to the study of the potential role of exposures to environmental agents such as air pollution and maternal use of medication such as selective serotonin reuptake inhibitors during brain development.

The scientists who study toxicology approach question regarding the safety of compounds and events living things are exposed to from the fields of biology, chemistry, medicine, and environmental science, among others. Neurotoxicologists study the effects of chemicals and environmental events on the brain and brain development.

Train-and-Hope Strategy

Geralyn Timler

Speech Pathology and Audiology, Miami University, Oxford, OH, USA

Definition

Intervention goals for individuals with autism spectrum disorders (ASD) often include increasing the use of one or more target skills within the treatment sessions. Moreover, comprehensive interventions include strategies to support the generalization of the new target skills. Generalization is the ability to use newly acquired skills with other materials, people (e.g., family members, teachers, peers), and settings (e.g., home, work, school, recess), that differ from the treatment sessions. The phrase “*train and hope*” was identified in Stokes and Baer’s (1977) classic review of treatment generalization strategies. “*Train and hope*” refers to teaching individuals a desired skill within a treatment session and hoping that the individual will generalize the use of that skill without implementation of a predetermined plan or strategy to facilitate generalization. Instead of merely “*hoping*” for generalization, Stokes and Baer (1977) recommended implementation of explicit and systematic strategies to promote generalization. These strategies include using sequential modification, training sufficient exemplars, programming common stimuli, using natural maintaining contingencies, training loosely, using indiscriminable contingencies, mediating generalization by teaching individuals to monitor their own performance, and training to generalize. Please see generalization and maintenance for an explanation of these generalization strategies.

Training Parents of Youth with Autism to Advocate for Adult Disability Services

Definition

Parents of individuals with autism spectrum disorder (ASD) often advocate throughout their lifespans on behalf of their offspring. An advocate is “someone who acts on someone’s behalf or for

their best interest” (Alper et al. 1995). With respect to individuals with ASD, parent advocacy can take on many forms ranging from advocating to access and obtain individual services to advocating for systemic changes to a service delivery system. With respect to adult services for individuals with ASD, parents’ knowledge about the adult service delivery system, feelings of empowerment, and skills to identify, access, and receive needed services can result in effective parent advocacy.

Historical Background

Upon aging out of special education services, individuals with ASD shift from an entitlement driven system (i.e., special education services) to an eligibility driven system (i.e., adult services). Although adult services exist, after exiting special education, many adults with ASD lack needed services (Shattuck et al. 2011). Without services, individuals with developmental disabilities, including ASD, may make little progress (Taylor and Hodapp 2012). Indeed, youth with ASD may go for years without needed services and rely on family to provide support.

Barriers to Receiving Adult Services for Youth with ASD

Although there are many barriers to accessing adult services, for brevity, only three barriers will be listed here. First, the adult service delivery system is fragmented. Comprised of a variety of agencies, services, and funding sources, the adult service delivery system stretches across multiple domains including but not limited to employment, health, leisure and recreation, housing or community living, financial assistance, and education. Different policies dictate regulations for certain adult services. Health services, for example, are (in part) outlined by the Patient Protection and Affordable Care Act while community living and housing services are (in part) regulated by Section 8 of the Housing Act of 1937. Further, in addition to having a variety of policies relate to different services, some policies overlap. For example, agencies that receive any federal

funding must comply with Section 504 of the American Rehabilitation Act, which provides accommodations and services to individuals with disabilities, including ASD. Such agencies could include post-secondary education institutions, places of employment, and leisure and recreational facilities as long as they receive some federal funding. Due to the fragmented nature of the service delivery system including the different policies and regulations, parents struggle to access and obtain services for their offspring with ASD.

Second, in addition to being fragmented, adult services are also complicated because, in some instances, certain policies and services impact one's eligibility and reception of other services. For example, in a given state, the Division of Vocational Rehabilitative Services generally helps individuals with disabilities, including ASD, find, secure, and maintain employment. Unfortunately, many states have waiting lists for Vocational Rehabilitative Services. Often, in these waiting lists, individuals with disabilities are prioritized by their level of needs. In some states, the level of need is, in part, determined by whether the individual is receiving supplemental security income (SSI). If the individual is receiving SSI, then the individual has a higher priority on the waiting list. Parents would have to learn how to navigate the SSI regulations to access Vocational Rehabilitative services. Thus, the onus is often put on parents to understand the rules of different service delivery systems as well as how the systems relate to one another.

Third and finally, adult services are difficult to navigate and receive because they are often eligibility driven. Parents of youth with ASD may have grown accustomed to their offspring being entitled to receive special education services, which are federally required regardless of the cost to the school. Adult services, however, are eligibility driven, meaning youth with ASD must qualify to receive services.

For example, youth with ASD may be eligible to receive a Home and Community Based Services (HCBS) Medicaid Waiver – this waiver reimburses states for providing supports including employment, transportation, and therapies. One issue with the HCBS Medicaid Waiver is that

43 out of 50 states have waiting lists for this waiver (Research and Training Center on Community Living 2013). Depending on the state, it could take years before a youth with ASD is eligible to receive a Medicaid Waiver. Further, eligibility for an HCBS waiver varies by state. In some states, an individual must have an intellectual disability to be eligible for the waiver, whereas other states require individuals to have a developmental disability (i.e., eligibility is not limited to an intellectual disability) to be eligible for the waiver. Thus, depending on the state, individuals with ASD may not even be eligible for the waiver. This issue of varying eligibility can lead to inter- and intrastate variation. Specifically, individuals with ASD may be “locked in” to residing in states where they are eligible for Medicaid waiver services feeling they are unable to move to a state wherein they would not be eligible.

Need for Parent Advocacy

Given that the onus is on parents to identify, access, and receive adult services for their offspring with ASD, parents need advocacy skills. When parents are knowledgeable and advocate for their children, parents report that transition planning and the subsequent shift to adult services is more seamless (Timmons et al. 2004). Yet, many parents of individuals with developmental disabilities, including ASD, report struggling to advocate and to understand the adult service delivery system (Hetherington et al. 2010). As such, there is a strong need for parent advocacy training interventions about adult services. Although the research about parent advocacy is scant, the limited extant research indicates that parent advocacy interventions lead to increases in knowledge and perceived advocacy skills to navigate service delivery systems (Burke et al. 2016).

Current Knowledge

Because the systems of services and supports for individuals with ASD who are moving from high school to adult life are very complex, it is important to understand what choices are available and

how enrollment in some services may affect access to other services. To help in the decision-making process for parents of young adults with ASD in Tennessee, a comprehensive 12-week parent advocacy curriculum, entitled the Volunteer Advocacy Program – Transition (VAP-T), is used to train parents. Funding for this work was received from the National Institute of Mental Health. The training provides information on various services and post-secondary, advocacy tips for parents of young adults with ASD, as well as a Letter of Intent form.

The Letter of Intent is not a legal document; it is a record of information about the person with a disability. This includes family information and a record of the other topics found in the VAP-T curriculum. Included in this document would be: the services and programs that have been applied for in the past, the outcome of those applications, and the programs and services that are currently in place. The information found in a Letter of Intent is important for anyone supporting a family member throughout his or her life-course. The document helps families plan and assess life-goals from year to year. Parents in the VAP-T are encouraged to complete a couple of pages of the Letter of Intent each week that coordinates with the topic covered. Notably, the Letter of Intent should be updated as changes occur and, otherwise, at least annually.

The 12 sessions in the VAP-T curriculum are 2.5 h each in consecutive weeks and are held in the evening to accommodate parents who often have active careers in this stage of family life. Because the sessions are offered during the dinner hour, a light meal or snack is provided. Each week's agenda includes PowerPoint presentations by subject matter experts, activities for participants, time for discussion among participants across three sites, and resources specific to the topic covered and the physical location of participants. Participants and facilitators in all locations received a notebook containing all materials, activity sheets, and resources.

The group facilitator and subject matter experts are present with a group at the host site. In collaboration with distance sites, the training is provided using video conferencing, so that two

other groups of parents can join remotely. Additionally, if participants cannot attend at the host or remote sites then, on occasion, they can join from a home computer. All sessions are video recorded for later viewing if a participant misses a session. Support to the remote sites includes a meeting before the start of the training to go over the curriculum, group facilitation techniques, and technology.

The 12-week curriculum includes the following topics:

1. Introduction to the Project – Syllabus, Speaker Information, Acronyms Guide, Letter of Intent
2. Person-Centered Thinking and Planning
3. Secondary Education
4. Supplemental Security Income (SSI)
5. Social Security Disability Income (SSDI) & Family Support Program
6. Employment 1 – Types, Training, Ticket to Work
7. Employment 2 – Vocational Rehab and the Workforce Innovation and Opportunity Act (WIOA)
8. Post-Secondary Education
9. Employment and Community First Program (i.e., a Medicaid Waiver Program)
10. Conservatorship & Special Needs Trusts, Achieving a Better Life Experience Act of 2014 (ABLE)
11. TennCare (Medicaid) and Medicare
12. Housing and Non-Adversarial Advocacy

During the development of the VAP-T curriculum, an advisory board consisting of parents, self-advocates, and community partners provided input and feedback on the syllabus and course content. The initial curriculum was provided to a pilot group of parents of adults with ASD at the host location only. Pilot group participants were individuals invited by members of the team and colleagues. Based on feedback of the pilot group, the curriculum was shortened, and then delivered it to a newly recruited group of participants that included the host and distance sites.

It is necessary to update the curriculum each time it is delivered, to reflect all policy changes,

eligibility changes, new programs, etc. It is also necessary to plan months in advance with speakers to fit into busy schedules and to identify new subject matter experts as people change positions or as new topics are added for new programs in the state.

Goals of the curriculum are that parents gain knowledge about services as well as gain greater confidence as advocates for their sons and daughters. Feedback from evaluations confirmed that those goals were met, even with parents who are highly engaged in the disability community and who were knowledgeable on various parts of the curriculum before participating in the training (Taylor et al. 2017). Additionally, families valued the opportunity to have discussions with representatives of local disability organizations and programs and to have their contact information. And finally, participants found value in getting to know other parents who are in various places along their journeys with their sons and daughters, learning from one another, and forming new relationships that could last beyond the group. This is an especially valuable outcome, since parents often feel isolated after their children leave the school system that had, for 12 plus years, put them in naturally occurring contact with other parents.

One of the biggest challenges is making this curriculum accessible to larger numbers of parents of transition-age sons and daughters with ASD. For example, a 2.5 h weekly commitment to attend a training session is not possible for some people. Also, some parents may not live close enough to join the in-person training or have broadband internet access to the training. In addition, the curriculum as written is specific to Tennessee. Some programs and services such as eligibility for SSI are the same in all states. However, some programs are specific to a given state such as how Medicaid dollars are allocated in programs that support people in the community, high school transition programs, and local post-secondary college programs, as well as others. These challenges make it difficult to determine how to scale-up the project to reach other families of individuals with ASD.

Future Directions

There are several next steps. One next step is to develop a curriculum that can be adopted nationally, state-by-state, in a format that provides flexibility in the way information is delivered. In this new curriculum, there will be video pre-recorded sessions that contain basic information about systems and services for each transition topic. This general information on each topic in the curriculum will include program and service descriptions and the information that is applicable in any state but would not contain state specific information. Parents will be able to view these recorded sessions on one topic each week. They can be viewed on-line, or the recordings can be shown to a group, in-person. An alternative format would be to provide a DVD of the presentations to individuals. All participants will receive course materials by email or in print.

At individual sites, the facilitators will identify local and state-wide subject matter experts to supplement the basic information. The experts may be from disability organizations and agencies; they would present on programs in their specific state. This type of presentation would follow the viewing of the basic information on the weekly topic. Facilitators will have the flexibility to offer the supplemental material in a variety of ways: to groups that are physically present; to groups who join remotely; or to individual participants that join from remote locations in an on-line classroom style. Each of these delivery methods provides the supportive benefit of the group experience.

In addition to offering access to the instructional materials in a variety of formats, future iterations of the curriculum should be adapted to be culturally responsive and available to diverse families. Although parent advocacy training interventions are needed for all families, these interventions may be especially needed for culturally diverse families as (compared to White families) they receive significantly less services (Magaña et al. 2013).

Collaboration with multicultural community programs and feedback from families of diverse backgrounds will be important in the development and delivery of culturally responsive training material.

Finally, a future step is to gather further data to show the value of providing this type of training to parents of youth with ASD. Having an evidence-based intervention like the VAP-T increases the likelihood that disability organizations and other partnering community organizations would be motivated to make this training available to parents. To increase capacity of parent advocates, a Train-The-Trainer (TTT) curriculum could be developed and technical assistance could be offered to support community investment in this type of project for parents of youth with ASD.

Transactional Support (SCERTS) Model

Danielle Geno Kent

The College of Arts and Sciences, The University of Vermont, Burlington, VT, USA

Definition

Social Communication Emotional Regulation Transactional Support (SCERTS) is an innovative educational model developed by Prizant et al. (1993). It is a lifespan model that is designed to help a child become a competent and confident social communicator, while reducing/preventing problematic behaviors that interfere with learning and the development of relationships. This comprehensive intervention approach is dedicated to facilitating the socioemotional and communication abilities of children with ASD in the context

of the home and school (Prizant et al. 2003; Prizant et al. 2004).

Historical Background

The SCERTS model was developed over two decades of clinical and empirical work and is consistent with recommended evidence-based practice (Prizant et al. 2003). The social-pragmatic framework of the model has been a focus of the researchers for several years. The model was developed in response to feedback/encouragement from clinicians and researchers in the field of ASD and also parents of children with ASD who were seeking an alternative route to the traditional education-based approaches. The model reflects an understanding of communication in ASD (both conventional and unconventional) that includes behavioral intentions and communicative functioning. The model is built on previous research supporting the relationship between social-emotional development, communication, and emotional regulation (Prizant 1999; Prizant et al. 1990; Prizant and Meyer 1993; Prizant and Wetherby 1990a, b).

Rationale or Underlying Theory

The SCERTS model emphasizes helping persons with autism to achieve “authentic progress,” which is defined as the ability to learn and spontaneously apply functional and relevant skills in a variety of settings and with a variety of partners. *Social communication* is referred to as the development of spontaneous and functional conversation and the building of secure and trusting relationships with adults. *Emotional regulation* is defined as the ability to maintain a well-regulated emotional state to cope with daily stressors. *Transactional support* is defined as the implementation of supports to respond to a child’s needs and interests. In addition, it helps partners modify and adapt the environment and enhances learning through the use of visual schedules and picture communication (Prizant et al. 2006a). The SCERTS model is a multidimensional approach

that allows professionals to continue using other therapy approaches (i.e., ABA) so long as they reflect one of the main components of SCERTS (social communication, emotional regulation, and transactional relationships). The SCERTS model also takes into consideration that most learning during childhood takes place in the context of daily social activities. With other models, there is often a gap in the support provided to those who serve as supports in the child’s life, such as para-professionals and parents. The SCERTS model takes into account this gap in the form of *transactional supports*, as the model considers the progress made by the child’s partners and how they are able to offer transactional support (i.e., learning supports) across contexts.

Goals and Objectives

The overarching goal of the SCERTS model is to provide children with the support to successfully participate in developmentally appropriate activities with peers, family members, and adult partners in a variety of settings (Prizant et al. 2003, 2004).

There are different goals for each of the three components of the SCERTS model. A sample of these goals is outlined below. Prizant et al. (2003) propounded several goals for each area that can be seen in full in their publication.

Research over the past two decades in the area of ASD has shown two major areas of challenge in terms of *social communication* that are addressed by the SCERTS model: the capacity for joint attention and the capacity for symbol use (Prizant et al. 2003). The capacity for joint attention is seen in a child’s ability to consider the attentional focus of another and to draw another’s attention to events/objects of mutual interest. This ability is considered to be the foundation for the development of language, social relationships, and social-conversational skills (Prizant et al.). The SCERTS model has three levels of goals for joint attention: the prelinguistic level, the emerging language level, and the advanced language level. At the prelinguistic level, goals include establishing shared affect, anticipatory behaviors (i.e., social referencing), and early intentional

behaviors, such as coordinating gestures with a physical gaze. Other goals at this level include increasing frequency/rate of communication bids, expanding the range of communicative functions, developing strategies for communication breakdowns, and developing the ability to communicate intent across persons, environments, and activities (Prizant et al.). The emerging language-level goals include expanding communicative intent, the ability to coordinate attention/affect through gaze, and increasing reciprocity. The advanced language-level joint attention goals include increasing the ability to communicate about past and future events, developing the ability to modify topic selections, and increasing the ability to interpret and use language flexibly (Prizant et al.).

The capacity for symbol use in children with ASD is typically impaired. It is seen through a limited ability to use conventional hand gestures (waving bye-bye, pointing), the use of unconventional vocal development and verbal behavior, and limitations in symbolic play and functional object use (Prizant et al. 2003). Goals at the prelinguistic level for symbol use include establishing consistent means for expressing intent, replacing unacceptable communicative means with acceptable ones, developing the use of more formal augmentative/alternative systems to communicate intentions, and developing the use of multiple gestural and vocal communication means (Prizant et al.). Goals at the emerging language level for symbol use include acquiring core vocabulary to serve a range of communicative functions, expanding vocabulary for semantic relations, expanding representational play themes, and expanding the ability to combine words to show semantic relationships. Goals at the advanced language level include achieving higher level linguistic forms that have differences in meaning (pronouns, tense markers, etc.), increasing the ability to use and interpret nonverbal behavior, and acquiring tools to use language as a tool for emotional regulation (Prizant et al.).

The SCERTS model targets *emotional regulation* by developing goals that are targeted toward the development of *self-regulatory* and *mutual-regulatory* abilities. There are two developmental levels of goals for self-regulatory and mutual-regulatory abilities: *prelinguistic/sensory-motor*

goals and *cognitive-linguistic goals*. Goals at the prelinguistic/sensory-motor level for self-regulation include increasing the child's ability to acquire and use sensory-motor strategies as supports and expanding the use of sensory-motor strategies to support transitions within daily routines. Goals at the cognitive-linguistic level for self-regulation include increasing the child's ability to initiate and utilize cognitive-linguistic strategies to support transitions through daily routines and expanding the ability to use cognitive-linguistic strategies to support attention throughout the day (Prizant et al. 2003). Goals at the *prelinguistic/sensory-motor level for mutual regulation* include increasing the ability to maintain engagement and attention to activities through responding to signs of dysfunction, increasing the ability to use socially acceptable gestures for social control functions, and developing strategies through nonspeech transactional supports to assist with the expression of arousal and emotional states (Prizant et al.). Goals at the cognitive-linguistic level for mutual regulation include increasing acquisitions of vocabulary that permits assistance requests and organizing supports when there is dysregulation, increasing the ability to use specific vocabulary for emotional/arousal state, and increasing the ability to identify and express emotional/arousal state and regulating strategies both with and without the use of a visual schedule (Prizant et al.).

The SCERTS model targets *transactional support* by making goals for *interpersonal support*, *educational and learning support*, and *family support*. Interpersonal support goals support the interactions between the target child and communication partners. Goals in this area include looking at the interaction styles of communication partners that support or serve as barriers to successful interactions, creating efforts across communication partners to use communication styles that support successful interactions, and designing and implementing peer-play interactions that support good language, social, and play models (Prizant et al. 2003). Goals for *educational and learning supports* include designing and implementing organizational and visual supports and designing learning/living environments that support emotional regulation and social communication. *Family support* includes providing

families with educational support to understand the nature of their child's disability and ways to support their child's development and providing emotional support in one-on-one and group settings (Prizant et al.).

Treatment Participants

Children with autism (up to 10 years old), in their preschool/elementary years, are the most appropriate participants. Although the intervention is targeted toward this population, it is not exclusive in nature. SCERTS can also benefit children with significant challenges in social communication and emotional regulation who need transactional support throughout the day. Children with developmental disabilities, communication disorders, and sensory-processing disorders who exhibit social communication and emotional regulation challenges could also benefit from the SCERTS model. Further, the model can be applied to verbal and nonverbal children (Prizant et al. 2003).

Treatment Procedures

The SCERTS model was designed to help professionals assess and establish goals based upon performance in the areas of social communication, emotional regulation, and transactional supports (see description under [Goals and Objectives](#)). The SCERTS Assessment Process (SAP) is considered to be an ongoing assessment process. It is designed to establish a profile of the child's strengths and needs, determine goals that are meaningful and motivational based upon their profile and functional skills, select appropriate teaching strategies and contexts for learning, determine the necessary level of transactional supports (whether it be learning support, support to families, or support among professionals), and monitor progress over time (Prizant et al. 2003).

Efficacy Information

Landsman (2007) did a review of Prizant et al. (2006) SCERTS manual. This review examined

volumes one and two. Volume one describes the SCERTS Assessment Process (SAP), and volume two explains the intervention component. Landsman (2007) states that one of the best features of the SCERTS manual is that it is practice and research driven, as opposed to other interventions that are purely research driven. There is very little research solely dedicated to the efficacy of SCERTS in practice, although the principles guiding the approach are grounded in research on what is known about social communication and emotional regulation.

Outcome Measurement

The SCERTS model uses an evolving assessment process. After the initial assessment of a child and goals are set, the child's progress in the areas of social communication and emotional regulation is monitored through daily logs, weekly logs, and also put into updated quarterlies. This ongoing monitoring of progress allows the team to assess if a child is making progress and if changes need to be made in transactional support. The data-collection procedure is not like other methodologies, as the SCERTS model data gathering involves not "one-on-one" response tracking forms but instead requires a consensus among team members about the child's performance and achievements with natural partners and across natural contexts. Core questions about social communication, emotional regulation, transactional support, and the relationship among the components of the SCERTS model are continually addressed during the process. The SCERTS model is "curriculum-based" or criterion-referenced. There is no normative data to compare a child's results; rather, a child's progress is tracked over time and compared to previously demonstrated skills or abilities.

Qualifications of Treatment Providers

The SCERTS model is most beneficial when it is initiated by an interdisciplinary team, as family members and professionals can contribute input that best addresses a child's needs. Providers

might include speech-language pathologists, general educators, special educators, and other related service providers (e.g., occupational therapist, nurse, social worker, psychologist, physical therapist).

Transition Cue

Definition

A transition cue can be any prompt given to an individual to represent or notify of an upcoming change from one activity to the next. Transition cues can be visual, verbal, auditory, or tangible and aim to pair concrete stimuli with a more abstract occasion. Using these cues helps to create a clear concrete representation of the transition as well as an established routine for recognizing and making the transition. Some examples of transition cues are ringing a bell or using a timer, singing a specific song, clapping hands or hand signals, picture cues, object cues, or any combination of these.

Transition Planning

Paul Wehman¹ and Staci Carr²

¹Department of Physical Medicine and Rehabilitation, Virginia Commonwealth University, Richmond, VA, USA

²UniqueKids Inc, Moseley, VA, USA

Definition

A legally required process for planning a student's transition services. During transition planning, the IEP team must discuss and decide whether the student needs transition services and activities (e.g., instruction, related services, community experiences) to prepare for the different domains of adulthood (postsecondary education, vocational education, employment, adult services, independent living, etc.) and if so set goals, develop strategies, and outline tasks and schedules to accomplish the goals in the student's individualized education program (IEP) or in some States on a document sometimes referred to as the Transition IEP or plan.

The focus within IDEA on school to adult life transition is an important step in improving adult outcomes for students with disabilities. As stated in IDEA §300.43, (a) *Transition services* means a coordinated set of activities for a child with a disability that-

1. Is designed to be within a result-oriented process, that is focused on improving the academic and functional achievement of the child with a disability to facilitate the child's movement from school to post-school activities, including postsecondary education, vocational education, integrated employment (including supported employment), continuing and adult education, adult services, independent living, or community participation;
2. Is based on the individual child's needs, taking into account the child's strengths, preferences, and interests; and includes-

- (i) Instruction;
- (ii) Related services;
- (iii) Community experiences;
- (iv) The development of employment and other post-school adult living objectives; and
- (v) If appropriate, acquisition of daily living skills and provision of a functional vocational evaluation.

(b) Transition services for children with disabilities may be special education, if provided as specially designed instruction, or a related service, if required to assist a child with a disability to benefit from special education.

From §300.320(b):

(b) *Transition services.* Beginning not later than the first IEP to be in effect when the child turns 16, or younger if determined appropriate by the IEP Team, and updated annually, thereafter, the IEP must include-

1. Appropriate measurable postsecondary goals based upon age appropriate transition assessments related to training, education, employment, and, where appropriate, independent living skills; and
2. The transition services (including courses of study) needed to assist the child in reaching those goals.

Historical Background

The transition from school to adulthood is critical in the lives of all students. For a student with autism spectrum disorder (ASD), transition of any kind can be challenging and the transition from school to postsecondary education or employment.

The curriculum for any student should be based on desired long-term outcomes. However, unlike their nondisabled peers, students with disabilities often seemed unprepared to achieve success as adults, despite the fact that they received special education. As a result, the Office of Special Education and Rehabilitation Services established transition as a priority and funding priority in the early 1980s.

Over the next 10 years time, Madeline Will proposed Bridges from School to Work as a conceptual model for transition and required transition planning. In addition, Halpern developed a conceptual model of transition. By the end of the decade, OSERS funded a Transition Study from 1987 to 1993 that included over 8,000 youth ages 13–21. In 1990, IDEA is passed and included provisions for transition services, and a systems change in transition priority was established in 1991. In 1992, the Rehabilitation Act was amended to include the same definition of transition as IDEA. In 1994, The School-to-Work Opportunities Act was passed that required the inclusion of all students. In 1996, the National Transition Alliance was funded to provide technical assistance to states to improve transition of outcomes of youth with disabilities. However, many states were too slow in implementing transition services requirements and failed to meet minimal levels of compliance (Johnson et al. 2002).

As mentioned earlier, transition services for students with disabilities were addressed for the first time in the 1990 amendment to the IDEA. Subsequent amendments to the IDEA have continued to strengthen and promote the vision for youth with disabilities to transition from education to employment and community living.

The IDEA 2004 reauthorization included requirements to develop and obtain measurable transition goals that articulate the intended post-graduation achievements of the student. This requirement went into effect July 1, 2005.

Transition planning has expanded since the 1980s from the narrow focus on a student's post-school environment which often focused only on employment to include curriculum and instruction to teach self-determination and work skills, and transition assessment systems and processes (Cobb and Alwell 2009). This evolution reflects emphases on the whole person and quality of life today.

Current Knowledge

Transition planning for a student with ASD should begin early in their academic career to

ensure appropriate planning of assessment, coursework, opportunities, and diploma status. For some students, this may be needed when they are young. The law, IDEA 2004, states transition planning is mandatory at age 16. Notably, by this time, coursework and diploma status has often been determined, thus limiting post-secondary opportunities for some students.

In order to systematically address transition services, the following three steps may prove useful: assessment to inform transition planning, development of goals and objectives, documentation and implementation.

During the assessment phase, assembly of key team members is significant to the success during the subsequent phases. Parents, teachers, and other support providers will work together to collect the necessary background documentation on the student. Assessments can be a variety of measures including formal assessments such as published assessments or checklists; informal assessments such as interviews, person-centered planning tools, or review of records; and clinical observations. Combined, these tools can be completed on an ongoing basis and offer a comprehensive picture of the student. These assessments are then used to inform transition planning.

Sitlington and Clark (2007) identified eight areas that should be considered when assessing the academic and functional performance of students:

1. Interests
2. Preferences
3. Cognitive development and academic achievement performance
4. Adaptive behavior
5. Interpersonal relationship skills
6. Emotional development and mental health
7. Employability and community skills
8. Community participation

While the components of the assessment vary based on the student's age and areas of individual need, a comprehensive assessment should include career awareness assessments, vocational evaluation and assessments, assessments of independent living and community skills, and assessment of self-determination.

Patton and Dunn (1997) indicated that there are two types of goals that can result from transition planning: instructional and linkages to community services and agencies. Cronin et al. (2008) note that both academic and functional skills need to be addressed.

Future Directions

With thoughtful planning and appropriate accommodations, the transition process for a student with autism can be clearer, which means less confusing and infinitely more successful. This is accomplished by following best practices and as needed using creative strategies to specifically address the behavioral and educational needs of a student with autism spectrum disorder (ASD). Autism presents as a compilation of characteristics that consist of sensory abnormalities and impairments in communication and social development. The severity of these characteristics falls along a continuum that generally determines the level of functioning of the student. The characteristics evident in ASD manifest in many ways including challenging behavior, difficulties in communication, and processing of information.

Challenging behaviors, particularly, can make transitions even more difficult to navigate successfully. Although students with ASD share many common characteristics, all students have unique strengths and needs that must be evaluated to inform transition planning.

Although self-determination training has been part of transition planning since IDEA 1999, today it is receiving much more attention such as writing self-advocacy goals in to the IEP related to transition. However, many special educators are not prepared to teach the skills of self-determination and do not know how to infuse them into the curriculum Wehmeyer et al. (2000).

Interagency and interdisciplinary planning is essential. However, in practice, professionals often overlook involving various adult agencies in transition planning (Patton 2004). And the requirement by law for vocational rehabilitation to be involved may not be adhered to by some. Family participation is also lacking. Transition planning is

not effective without family involvement. Furthermore, they are not able to benefit from it.

Sitlington (2008) states research is needed to examine and document the effectiveness of major approaches to instructing adolescents with disabilities. A review of transition literature by Test et al. (2009) reports no or limited studies addressing these issues. Furthermore, even in the realm of best practices, these are rarely implemented. Future research should provide empirical evidence of best practices. Sitlington (2008) goes on to also state that research should consider variables related to all aspects of adult living in follow-along studies and relate individual's education and transition planning experiences to follow-along findings.

Transitional Living

Anne Holmes
Eden Autism Services, Princeton, NJ, USA

Definition

Transitional living is a type of living arrangement in which an individual is learning a new way of life in preparation for going out on their own. This living

model allows an individual to be taught how to gradually ease into the process of conducting their life in a different, more productive way.

Many older teenagers and young adults with autism spectrum disorders, specifically high-functioning autism or Asperger's disorder, struggle with the social competencies and adaptive skills that are necessary to live independently, work successfully, and enjoy their community. Transitional living provides these individuals with an environment that focuses on teaching and supporting these critical skills, with the opportunity to use and practice these skills across multiple settings and with diverse populations. Fading of supports needs to be gradual, with opportunities for feedback.

It is also important that, once the individual with autism spectrum disorder has transitioned into an independent living arrangement, monitoring and feedback continue in order to promote success and address issues that may compromise that success.

Travel Training

Ernst O. VanBergeijk

Vocational Independence Program, New York
Institute of Technology, Central Islip, NY, USA

Cambridge, MA, USA

Definition

Travel training is a systematic approach to teaching individuals on the autism spectrum to use mass transit. According to Groce (1996a), "Travel training is short term, comprehensive, intensive instruction designed to teach students with disabilities how to travel safely and independently on public transportation. The goal of travel training is to train students to travel independently to a regularly visited destination and back" (p. 2). Without the ability to travel independently, an individual with autism is isolated and must rely upon others to transport them to work, social activities, and other activities of daily living (e.g., grocery shopping).

Historical Background

The history of travel training is scant at best. With the passage of the Individuals with Disabilities Education Act (IDEA) in the 1990s, educators acknowledged the need to train individuals with disabilities regarding how to access and use public transportation to increase their independence and employability. Publications were primarily in the form of newsletters and were written by special educators in large urban settings that had well-established public mass transit systems. Individuals with autism were not specifically studied nor were they specifically commented upon regarding a need for specialized instruction. Individuals on the spectrum were simply subsumed under the general category of individuals with developmental disabilities.

Current Knowledge

Driving an automobile is a highly complex skill that requires the ability to read or predict the intentions of other drivers. It also requires drivers to make instantaneous decisions when other vehicles drive in a manner that breaks the rules of the road or drive in an unpredictable manner. Individuals with autism have been described as having a lack of theory of mind (ToM) or the ability to predict the actions or intentions of others. Consequently, many individuals, even those that are higher functioning on the autism spectrum, will not learn how to drive. This severely limits a person socially and economically. According to the National Center on Workforce and Disability, the lack of reliable transportation is one of the most significant barriers to employment to individuals with a variety of disabilities (NCWD 2011).

Therefore, travel training skills are essential in maximizing the employability and independence of individuals on the autism spectrum.

Travel training must be broken down into subsets of skills that should be taught and learned in a developmentally sequential and appropriate manner. Three meta-skills that need to be assessed and mastered prior to independent travel are “(1) Awareness of personal space – meaning a clear understanding of where their personal space ends and others begins. . . ; (2) An awareness of their environment. . . ; and (3) The ability to recognize and respond to danger” (Groce 1996b, p. 10). Before travel training can begin in earnest, a child on the autism spectrum should be taught basic pedestrian skills including walking in a crosswalk, looking both ways when crossing the street, using pedestrian crossings with “Walk” and “Don’t Walk” signs and symbols, etc. In vivo practice crossing the streets is essential, and observations of pedestrian safety skills should be conducted. Some individuals on the autism spectrum because of their literalness or concreteness have been observed to wait for an extraordinary length of time for a crosswalk light to change because they did not realize that they had to push a button to activate the crosswalk light. Others have frozen in a panic because the light

changed from “Walk” to “Don’t Walk” while they were in the middle of the street. Although pedestrians legally have the right of way, they are still at risk of being struck by a motor vehicle even in a crosswalk. In one New York City study, 40% of pedestrians were struck by a car while walking in a crosswalk and accounted for 52% of all traffic fatalities (Solomonow and Gastel 2010). Individuals on the autism need to learn to anticipate the possibility of a car running a red light and must continuously scan the environment for danger. Confusion concerning what to do when a traffic light malfunctions also needs to be dealt with in training as well as developing the individual’s problem-solving skills. Reading basic traffic signs should be incorporated in pedestrian skills training.

For a child on the autism spectrum, part of the difficulty will lie in the area of sensory integration issues. Public transportation is often loud, crowded, and noisy. Smells of bus fumes and odors on the subway platforms can overwhelm even the most hardened traveler. Parents can help a child on the autism spectrum by previewing the sights, sounds, and smells for their child prior to traveling on the subway, train, or bus. Children that are hypersensitive to sound may use a MP3 player or ear plugs as a means of coping with the high-pitched sounds of brakes or pneumatic lowering devices found on city busses. A child who is hypersensitive to smell can use a handkerchief perhaps coated with a soothing scent to cope with the smells of a subway platform. With young children on the autism spectrum, the initial goals of traveling on mass transit are simply to habituate them to the sensory experiences associated with public transportation.

By incorporating the use of mass transit in the family’s daily life, the child with autism will have an easier time transitioning from traveling with his or her family to traveling independently. Parents should use public transportation in planning fun outings for the family to the beach, a museum, a baseball game, or some activity that is of particular interest to the child on the spectrum. Pairing the use of public transportation with fun and interesting activities for the child will help increase the probability of success. Early

trips with the young child should emphasize safety and problem-solving skills (e.g., not standing too close to the edge of the platform or the curb; procedures to enact should the child become separated from his parents while on a subway train versus a bus; and how to identify appropriate people to ask for help) (VanBergeijk 2009a). A natural show-and-tell approach by parents with their children can be used on daily outings on mass transit. Parents can name parts of the bus or train such as the stop request button or cord, exit, etc. and show the child familiar landmarks along frequently traveled routes especially those right before a destination stop. These natural teachable moments should include locating route maps and neighborhood maps. Learning to read these maps and general navigation skills are critical subskills to independent travel.

As the child ages, the trips should shift from parent-led to child-led outings. In this approach, the parent becomes the pupil, and the child shows the parent where to safely stand, find maps, locate schedules, and review procedures of what to do if separated. During this phase of parent-led travel training, pretravel planning can be introduced. Here, the parent can show the child how to locate information using the Internet regarding types of transportation to take, routes to follow, transfers involved, schedules, and varying fares. Not only should the child learn how to locate information reading the local transit system or regional rail travel, but they should also learn to use commercially available GPS/mapping sites or route-optimizing web sites. This will increase the child's sense of mastery and decrease their anxiety regarding travel.

Some higher functioning individuals on the autism spectrum such as those with Asperger syndrome will use their profound rote memorization skills to memorize subway maps and schedules. This can give parents a false sense of security that their child "knows" how to travel independently. The child will also believe he or she knows everything there is to know about traveling independently. What should be practiced and even staged are changes in service or "missed" trains and busses. These unexpected service interruptions or changes in the routine of schedule

can lead to meltdowns or panic. Practicing problem-solving skills in these situations is critical in training individuals on the autism spectrum to travel independently. The use of cell phones with preprogrammed telephone numbers should be practiced. During a meltdown or panic attack, the individual may not remember even frequently dialed telephone numbers. Well-labeled speed dial numbers will help alleviate some of the panic associated with a sudden and unexpected change in schedule or service.

At what age a child should travel or begin to learn to travel independently depends upon the developmental and cognitive level of the child. The child who appears to have mastered the aforementioned skills may be ready to try short tests. Since travel training is a complex skill, parents will need to use successive approximations to shape this behavior. As the child reaches junior high or high school age and if they are cognitively and developmentally able, the child can travel alone one stop along a well-traveled and known subway or bus route. Older siblings and other relatives can help in the process by waiting ahead of time at the destination while the parent(s) put the student on the subway or bus. The number of stops an older child travels alone can be increased along the well-traveled route as his or her confidence increases until the child has increased the number of stops traveled without parents to a desired destination. One suggested final destination to practice traveling to is the child's school. The child on the autism spectrum should be explicitly taught to travel with at least one other person or travel with groups of people. Enlisting willing classmates to travel with the child on the spectrum will help increase safety and normalize the experience of traveling to school without one's parent. Once the older child on the autism spectrum has mastered the familiar trip to school, other frequently traveled routes should be also traveled alone in successively longer intervals between stops. Finally, practicing transfers between busses and subways is an even more complex skill that should be attempted after mastering single modes of transportation.

Training using fixed route transit as described above or using paratransit systems offered

by schools or offices of developmental disabilities or vocational rehabilitative services should be considered when parents are not successful training their children to travel independently. The formal travel training can be incorporated into a student's individualized education plan as a part of a formal transition plan beginning at age 14 under the Individuals with Disabilities Education Act. Postgraduation or after the age of 21 years old, formal travel training will be the responsibility of either the state's vocational rehabilitative services office or state office of developmental disabilities.

Voorhees (1996) described a seven-phase process that formal travel training programs should employ when working with individuals with a variety of cognitive disabilities. These phases include the following:

- Phase 1: instruction in detail of specific route-related skills such as pedestrian skills, paying fares, interacting with community workers and strangers, and appropriate behaviors in public.
- Phase 2: observation and verification by a travel trainer of the skills learned in phase 1.
- Phase 3: emergency procedures training (e.g., missing a bus or train, losing a fare card, getting on the wrong bus or train, etc.).
- Phase 4: assessment of a student's skills in dealing with strangers.
- Phase 5: involves the student being observed from a distance by a travel trainer with the student's full knowledge of the travel trainer's presence.
- Phase 6: the student is observed covertly and with no knowledge of the observation and assessment of his or her skills.
- Phase 7: follow-up covert observations on a periodic basis.

A formalized program of this nature can be implemented by the school district, a state office of vocational rehabilitative services, or a social service agency subcontracted by the state to provide those services. Aspects of formal travel training programs may also be a part of the curriculum at college-based comprehensive transition programs.

Learning travel training skills are essential for individuals on the autism spectrum in order

for them to fully integrate into adult life and independent living. This is self-evident to many people. However, traveling for pleasure may not appear as an obvious need. Traveling for pleasure both domestically and overseas helps to increase the quality of life for individuals with ASDs. It provides them with opportunities to learn new skills, try new foods, make friendships, and accumulate fond memories which can be the basis for conversations with new people they meet.

Traveling for pleasure for individuals on the spectrum often involves family vacations. As the child grows older, he or she can join summer travel programs for individuals with ASDs or other types of disabilities. Many of these summer travel programs are affiliated with summer camps that serve a wide variety of campers with disabilities. Often, these are returning campers who are older and are looking for new experiences. Other travel programs that are for pleasure are offered by postsecondary independent living programs or comprehensive transition programs.

The traveling for pleasure programs can build upon travel training programs that aid individuals in traveling to and from home and work. Some programs simply offer guided tours with no specific curriculum. Others offer a more formalized curriculum which could begin months before the actual trip overseas.

The curriculum can include the following aspects: (1) how to apply for a passport and/or a visa; (2) how to use public transportation to reach the airport; (3) the purchasing of tickets, tours, and accommodations; (4) packing suitcases with appropriate clothing for a trip; (5) what to expect when going through airport security; (6) how to answer airport security questions; (7) words or phrases not to use in an airport or aboard an airplane; (8) forbidden items not to pack in a suitcase or bring aboard an airplane; (9) monetary exchanges; (10) personal safety when traveling abroad; (11) completing customs declaration forms; (12) the use of international calling cards; (13) dealing with jet lag; (14) local natural and historic sites of interest; (15) cultural do's and don'ts; and (16) cuisine of the destination country. As a way to both quell anxieties and stoke positive anticipation of an upcoming trip, some international travel training programs host an event

prior to the trip in order to introduce traveling companions to each other, show a slide show of points of interest in the destination country to group members, and serve a dinner featuring foods from the country where the group will be traveling. Many individuals on the spectrum have limited palates or food choices and will be anxious about what they will eat or drink. By hosting a dinner with the foods they may encounter on the trip, the program helps reduce the individual's anticipatory anxiety over food and helps them identify foods they may like to eat on the trip.

When choosing an international travel training trip for an individual on the spectrum, it is important to assess how the program will provide participants with structure, predictability, and safety. The ratio of chaperones to participants will depend upon the level of functioning of the participants. The lower the level of functioning, the lower the ratio of chaperones to participants should be. While traveling, the group should be further subdivided into units where a chaperone is solely responsible for the whereabouts of a smaller number of individuals. Throughout the day, the group leader should ask chaperones to conduct a head count. The group leader should structure the day so that each day is similar (e.g., wake up calls and breakfast set at the same time, early morning preview meeting of the day's activities, early evening debriefing meeting with a preview of the following day's activities, escorting the participants to pay phones to call home at the same time and providing assistance with calling cards, etc.). The group leader will have to review emergency procedures with the group such as what to do if lost and hand each participant a business card with the name of the hotel that the group is staying at and insure the participant places the card in his or her wallet that he or she carries at all times. Periodically, the group leader will also have to remind participants about taking care of their daily hygiene, dress codes for different venues, and taking prescribed medications. With a change in time zones, participants can become particularly confused about when to take their medications. Staff must help them transition to the new time zone and new schedule of taking medications. When engaged in adventure

activities (e.g., zip lining, snorkeling, outrigger canoeing, etc.), participants should be given an option that does not involve a perceived risk. Some chaperones should offer an alternative activity that they supervise while the other group members engage in the adventure activity.

Finding a travel program for individuals with any kind of disability can be a challenge. Airports are beginning to offer programs to families with children on the spectrum to help them cope with the stressors of travel (Strunsky 2011; WALB News 2011). Some boarding schools and comprehensive transition programs offer this type of programming as an extracurricular activity (VanBergeijk 2009a). The National Clearinghouse on Disability and Exchange provides information regarding foreign student exchange (Mobility International USA 2011). Using the Internet search engines with keyword searches such as "special needs camps and travel" or some other similar phrasing will yield a list of camps and travel programs which cater to individuals with disabilities.

Teaching an individual travel training skills is essential to his or her independence. It increases the person's freedom and overall quality of life. Mastery of travel training skills also contributes to an individual's increased self-esteem. This is a complex skill that can be taught systematically throughout a person's development. Refresher sessions may be necessary as changes occur in public transportation.

Future Directions

There is very little research in the field of travel training. The majority of recently published studies focus upon individuals with physical disabilities with a particular emphasis upon individuals with visual impairments. Currently, there are no published research studies that are specific to individuals on the autism spectrum. In the future, research studies should focus upon this population and conduct efficacy-based research comparing parent-led training versus curricula developed by social service and employment agencies and by school districts. Distinctions should be made in the research between fixed route travel skills using

mass transit or paratransit services, flexible route travel training skills, and travel for pleasure skills.

Travel training for employment and independent living skills should be incorporated in a student's individualized education plan (IEP) under the Individuals with Disabilities Education Act (IDEA) or as a part of an individualized plan for employment (IPE). The travel training can be added to the IEP as a part of the transition plan when the student reaches age 14. Pedestrian and other safety skills can be added to the IEP earlier in the process. The trend in the future will be that travel training will be more often formally incorporated into IEPs and IPEs as parents become aware of this possibility.

Definition

Trazodone is an older antidepressant medication that has a mixed mechanism of action affecting multiple neurotransmitter systems. It is often used in adults as an adjunctive treatment for depression, particularly to aid with sleep. It has not been evaluated in children or adults with autism. The use of trazodone is avoided in males due to multiple reports of priapism. Priapism is an acute problem characterized by prolonged and painful erection.

Treatment and Education of Autistic and Related Communication-Handicapped Children

Victoria Shea

Department of Psychiatry, TEACCH Autism Program, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Definition

TEACCH was originally an acronym for *Treatment and Education of Autistic and related Communication-handicapped CHildren* (although TEACCH now serves individuals of all ages). TEACCH is based at the University of North Carolina at Chapel Hill and is a nationally and internationally known model of conceptualizing autism spectrum disorders (ASD) and delivering services and supports (Mesibov et al. 2005).

Historical Background

TEACCH began at the University of North Carolina at Chapel Hill in 1972 as a continuation and expansion of a federally funded grant to the late Eric Schopler, Ph.D. for clinical work with children with autism and their families. When the federal grant ended, Dr. Schopler and the families successfully lobbied the North Carolina General Assembly to continue funding the program. TEACCH now includes regional centers across North Carolina that provide diagnostic evaluations, parent coaching, social and support groups, and other clinical services. TEACCH also operates model early intervention and supported employment programs and a residential/vocational program (the Carolina Living and Learning Center) and provides individual consultations and professional training workshops. The directorship of TEACCH passed from Dr. Schopler to Gary Mesibov, Ph.D. in 1993 and then to Laura Klinger, Ph.D. in 2011.

Rationale or Underlying Theory

TEACCH developed the concept of the “Culture of Autism” to convey the idea that like cultures, autism spectrum disorders yield characteristic patterns of thinking, communicating, and behaving. This concept is broader than, although compatible with, standard diagnostic criteria. TEACCH proposes that teachers, therapists, and parents should function as “cross-cultural interpreters” who translate the expectations of the neurotypical world into forms that people with ASD understand. Therefore, understanding the Culture of Autism is a prerequisite for developing the most effective interventions.

Features of the Culture of Autism include (1) scattered cognitive skills, with relative strengths in visual understanding and relative weakness in auditory processing; (2) tendency to focus on details rather than on the underlying, integrated meaning of the details (i.e., limited central coherence; Frith 2003); (3) distractibility or other atypical patterns of focusing and disengaging attention; (4) difficulties with generating organizational strategies; (5) limited ability to understand the perspectives and experiences of other people; (6) difficulties with generalizing from one situation to another; (7) difficulties with time concepts and sequencing in time; (8) atypically strong interests and impulses; and (9) sensory and perceptual differences. Many individuals with ASD also have excessive levels of anxiety. Further, all have some form of communication disorder, which varies across individuals, ranging from no speech and extremely limited receptive language to excessive, awkward speech and occasional receptive difficulty with nonliteral communication such as “body language,” verbal sarcasm, and idioms.

Goals and Objectives

The TEACCH approach involves strategies both for teaching new skills and for designing environmental supports. One long-term goal of the TEACCH approach is developing skills for daily living so that individuals function with the highest

possible degree of independence given their neuropsychological impairments. Other goals involve meeting fundamental human needs of engagement in productive, personally meaningful activities and feelings of dignity and security.

Treatment Participants

The TEACCH approach is appropriate for individuals with ASD at all ages and functioning levels. It can be used to help individuals with ASD learn new skills or participate appropriately in any setting, including, but not limited to:

- Schools and child care centers (from preschool to graduate school, from special education settings to typical classes)
- Home (e.g., learning to participate in chores, mealtimes, leisure time, homework)
- Community activities and errands (e.g., standing in a checkout line, sitting through a religious service, participating in grocery shopping, getting a haircut)
- Medical, dental, and therapy appointments (e.g., remaining cooperative through the steps involved in examination or treatment, following the sequence of activities in speech/language or occupational therapy sessions)
- Work sites (e.g., competitive employment, supported employment, volunteer work with a job coach, sheltered employment settings)

Treatment Procedures

The overall TEACCH approach is called “Structured TEACCHing.” The fundamental principles of Structured TEACCHing are:

- Individualize interventions based on the person’s specific pattern of difficulty, strengths, and special interests.
- Use visual or written supports to supplement auditory language-based information.
- Make the sequence of events predictable and understandable using visual means, such as a schedule of upcoming activities (depending on

the individual's skills, this may take the form of objects, picture, or written words).

- Organize the physical environment and visually highlight important features of both the surroundings (such as where to sit, stand, walk, drive, etc.) and tasks (such as where to focus attention or put materials).
- Work specifically on flexibility and generalization by changing the sequence of activities and introducing new elements (e.g., location, materials, staff or peers, etc.).
- Stimulate and support meaningful, self-initiated communication (in contrast to prompted speech or rote memory).
- Collaborate with families.

TEACCH Structured TEACCHing suggests that for teaching new skills or in situations of behavioral difficulties, visual answers should be provided for the following questions:

- Where am I supposed to be?
- What am I supposed to do?
- How much will I do? How long will I do this?
- How can I see that I am making progress, and how can I see that I have finished?
- What will I do next?

Techniques for answering these questions vary widely based on the individual's age and skill level and the setting. For young and developmentally delayed learners, typical techniques for answering "where" include defining learning spaces through furniture placement and blocking out sources of distraction. For older and developmentally advanced individuals, it is often useful to provide visual guidance (or options) about where to sit, where to put possessions, and how to get from place to place in the school or work setting.

Techniques for showing "what" generally involve clear visual directions (often accompanied with brief verbal directions) about the steps in the task and the sequence of tasks to be completed. For example, a developmentally young learner might have a system consisting of different shapes on his worktable. Each shape would correspond to a shape on a box containing a task. The person would know *what* task to do by taking a

shape from the table and matching it to the box with the same shape. The person would know *how much* work there was by the number of shapes on the worktable. For example, if there were three shapes, that would mean there were three tasks to complete during the work session. *Progress* would be understood by seeing the shapes on the table decrease and seeing the boxes moving into the finished area as tasks were completed. The person would know that the session was *finished* when all of the shapes had been removed from the worktable. A more developmentally advanced person might have a written system with a list of tasks labeled in words (such as "science, PE, social studies" or "staple, fold, insert into envelope, sort by zip code"). The individual would know *what* to do based on the written words corresponding to the labels on each of the books, folders, or other containers in the work area. *How much* work would be seen by the number of items written on the list or by a written indication of the time the activity would end. The person would see that *progress* was being made as each item on the list was crossed off. When all the words were crossed off, that would be the sign that the work was *finished*.

Techniques for showing "how much" or "how long" include (1) having materials organized into containers that become emptier as the task moves toward completion, (2) having a list of activities that are checked off or removed as they are completed, and (3) using a visual timer that provides information about the passage of time and arrival of the end of the activity. Consistent with these techniques, "finished" is shown by empty containers of materials, a completed checklist, or a visual and/or auditory cue from a timer or clock. When activities are completed, there is typically a mechanism for guiding the individual to engage in a leisure time activity or to look back to the schedule to find the next activity.

Efficacy Information

A current trend in psychology and related disciplines suggests that randomized controlled trials (RCTs) are the best way to demonstrate efficacy.

(In an RCT, a single variable is manipulated, while all other factors are effectively neutralized through random assignment of subjects to treatment or control groups.) However, the RCT methodology is not universally accepted as the best approach for assessing comprehensive ASD treatment programs (Mesibov and Shea 2011; Reichow et al. 2011), and there are currently no published RCTs of TEACCH versus other methodologies, although one quasi-experimental study is in progress (Odom 2007). Several recent studies using other research methodologies have provided evidence of the efficacy of Structured TEACCHing techniques (Mesibov and Shea 2010). Also, the National Standards Report (National Autism Center 2009) identified Structured TEACCHing by name as an “emerging treatment” and called several components of Structured TEACCHing “established treatments” – specifically Antecedent Packages and Schedules. Similarly, the National Professional Development Center on Autism Spectrum Disorders (<http://autismpdc.fpg.unc.edu/content/briefs>) lists as “Evidence-Based Practices for Children and Youth with ASD” the following Structured TEACCHing practices: Antecedent-Based Interventions, Structured Work Systems, and Visual Supports, in addition to widely used practices also used at TEACCH such as prompting, reinforcement, task analysis, functional communication training, social narratives, and parent-implemented training.

Outcome Measurement

Adult outcome research in the field of ASD has included various measures, including standardized test scores (cognitive, language, academic, adaptive, etc.); attainment of an academic high school diploma or college degree; living arrangements; employment status, wages, and benefits; number and quality of social interactions; and individual ratings of life satisfaction (Howlin 2005; Shea and Mesibov 2005). However, long-term outcome research is fairly limited, and there are no peer-reviewed studies comparing the outcome in adulthood of individuals treated in childhood with different treatment approaches.

Qualifications of Treatment Providers

TEACCH center directors have historically been doctoral-level clinical psychologists. The staffs at the centers come from a variety of backgrounds including education, psychology, rehabilitation counseling, social work, and being the parent of a child with ASD. There are no specific licensure requirements.

Treatment Fidelity

Synonyms

Accuracy of treatment implementation; Fidelity of implementation; Intervention integrity; Procedural fidelity; Trainer implementation; Treatment adherence; Treatment integrity

Definition

The degree to which a treatment condition is implemented as intended. It refers to whether the treatment condition manipulated the independent variable as planned and is an important methodological component in empirical interventions. A high level of treatment fidelity requires adequate staff training, adherence to intervention procedures, and ongoing support and monitoring of

implementation. Treatment manuals are typically provided to allow for written descriptions of the intervention procedures. Treatment fidelity data and reliability should be provided within scientific reports of a treatment evaluation. It is critical that treatments are routinely assessed for treatment fidelity to ensure that the process is standardized and consistent. Furthermore, the level of treatment fidelity is a factor in treatment replication and generalization across settings.

Treatment for Higher-Order Restricted, Repetitive Behaviors

Definition

Treatments for higher-order restricted, repetitive behaviors (H-RRBs) aim to improve the skills of people with ASD to appropriately vary their behaviors and interests to situational demands. Specifically, to adaptively vary from following preferred idiosyncratic rituals or routines, shift one's activities and topics of conversations from restricted interests, reasonably adjust to changes in routines and schedules, and vary from engaging in repetitive play actions. These treatments focus on addressing impairments in behavioral flexibility observed in many people with ASD. Interventions targeting H-RRBs are aimed to promote skills in flexibly adjusting to situational demands while teaching skills, either directly or indirectly, to appropriately regulate emotions and behaviors to improve the overall adaptability of people with ASD.

Higher-order restricted, repetitive behaviors are considered to be distinct from sensory motor repetitive behaviors given that these sets of behaviors and interests seem to be cognitively mediated rather than driven by sensory and repetitive motor movement needs. In fact, there is evidence indicating that H-RRBs are not as heavily influenced by developmental and language factors as sensory and repetitive motor behaviors are, indicating that H-RRBs may be unique characteristics of ASD, rather than a function of developmental delay.

The rationale for an intervention to target this subcomponent of restricted repetitive behaviors (RRBs) is that impairments in behavior flexibility can contribute to increased functional impairment for people with ASD and their families. Challenges with adaptively and flexibly adjusting from preferred interests and behaviors are associated with emotion dysregulation and behavior problems that can contribute to functional impairment across many areas of life. In children, impairments stemming for H-RRBs have been associated with interfering with social, communication, and adaptive functioning. Difficulty varying from preferred interests and behaviors and appropriately adjusting to situational demands

have been linked with negatively affecting peer and family interactions, interfering with the completion of daily activities in the home, and limiting the overall learning opportunities of people with ASD (e.g., early academic learning).

Developmentally, insistence on sameness behaviors (e.g., need to follow idiosyncratic changes, difficulty with changes) seems to be a common aspect of childhood that begins to emerge and peak in the preschool years and then becomes less prominent as children exit their elementary-school age years. However, in ASD, the degree of emotional reactivity and behavior challenges associated with varying from these interests and behaviors is more frequent and severe and can persist longer across the life span in comparison to typical development. In addition, although these behaviors and interests can be a source of positive feelings and comfort for all people, particularly those with ASD, the emotional and behavioral challenges that arise for people with ASD when they are faced with situations that differ from their H-RRBs can be very limiting and cause a greater degree of distress than that of typically developing people.

Interventions that specifically target behavior flexibility are emerging either as the singular focus or as part of a broader intervention package that spends a portion of the treatment targeting H-RRBs. The interventions commonly include behavioral intervention strategies based on the principles of applied behavior analysis (ABA), such as teaching replacement behaviors, shaping, and differential reinforcement. Some of these interventions are also including additional treatment strategies such as cognitive reappraisal and emotional regulation skills that aim to improve behavior flexibility. These more recent aspects include skill building in the development of adaptive thoughts, problem-solving strategies, and coping strategies. Intervention modalities include group intervention, individual child treatment, and parent-mediated intervention.

As of now additional research on further understanding H-RRBs and the development of effective and empirically supported interventions

targeting this symptom domain of ASD continue to be a growing need. Historically, the focus of the field has been on the social-communication challenges inherent in ASD and developing treatments to target improvement in this area of functioning. Therefore, interventions targeting H-RRBs have been slower to develop, but has been gaining more momentum as the understanding of the impact and nature of H-RRBs has been evolving.

Treatment preference assessment

Definition

Treatment preference evaluation is a procedure used to examine the preference between two or more treatment alternatives for individuals with autism and other developmental disabilities. Results of the treatment preference evaluation can help professionals establish treatment acceptability and social validity (Kodak et al. 2016; Yuan et al. 2019). During the evaluation, the individuals are first guided to choose and experience each treatment to ensure that they have been exposed to the options before they make their selection (Hanley et al. 1997). Then, they are asked to choose their preferred treatment followed by the selected treatment session. During the evaluations, the more preferred treatment will have more selections. Previous studies have used this evaluation procedure to reveal preferences of children with autism for various procedures such as response redirection and blocking (Giles et al. 2012) as well as different error-correction arrangements (Kodak et al. 2016; Yuan et al. 2019). Visual stimuli (e.g., colored paper) representing different treatment options were used in these studies for children to make the selections. Presenting treatment alternatives in the visual forms may be particularly useful for those who have limited verbal communication skills so that they can express preferences by

selecting the associated visual stimuli (Yuan et al. 2019).

Even though alternative assessments of treatment acceptability using rating scales and questionnaires can also be completed by stakeholders such as parents and practitioners and may provide valuable input, preferences and values of the stakeholders may not always align with those of the individuals who directly receive the treatment (Hanley et al. 2005). Indeed, existing literature reports that individuals with autism and developmental disabilities sometimes prefer the treatment alternatives that may not be obvious to others (e.g., Hanley et al. 2005; Yuan et al. 2019). Additionally, individual preference may also have an impact on treatment efficacy (Kodak et al. 2016; Yuan et al. 2019). For example, a preferred treatment could lead to a higher level of compliance and engagement. Coupled with effective treatment, the high level of engagement might result in an even greater likelihood of success. By contrast, a treatment that is not preferred can produce noncompliance and problem behavior (Yuan et al. 2019). Thus, practitioners should include opportunities for individuals with autism to show their treatment preferences during the treatment-selection process, especially when the treatment alternatives are equally viable and may produce similar effects.

²Koegel Autism Center, Eli and Edythe L. Broad Center for Asperger Research, University of California, Santa Barbara, CA, USA

Definition

Treatment priorities must be individualized and consider the unique needs of the individual with autism as well as the needs of the relevant stakeholders in the individual's natural environments. Particularly important in developing treatment priorities is social validation or the concept that the most important and beneficial behaviors to teach should result in a valuable and meaningful difference in the individual's life. It is recommended that the individual with autism's own personal goals and expectations are addressed and incorporated accordingly into the treatment plan. The treatment priorities of the parents or caretakers for the individual with autism are also an important aspect of intervention, and their concerns should be taken into account. In order to address this issue, it is important that the individuals themselves, their parents, caretakers, and other members of the individual's support group actively partake in contributing to the treatment priorities. Research suggests that

parents and caretakers rank skills such as making friends, pedestrian safety skills, and appropriate interaction skills as a part of their top ten priorities in the treatment outcome of the individual with autism. Thus, treatment priorities relating to safety, social skills, communication, and academics, among others, should be addressed.

All treatment priority goals should include quantifiable variables so that response to intervention and the intervention itself can be empirically and objectively evaluated. The success of treatment should not be contingent merely on the reduction of negative behavior but also on the increase of and improvements in positive behaviors.

The acceptability and ease of intervention implementation for the individual with autism must also be considered so that treatment is introduced as smoothly and efficiently as possible. Intervention procedures should always be executed in a way such that the individual with autism is treated with respect and dignity. Moreover, interventions should reflect an individualized and age-appropriate treatment plan in order to facilitate optimal social integration with peer groups. In addition, the implementation of treatment should be achieved in a naturalistic and comfortable way so that intervention can be executed consistently and frequently throughout the waking hours of the individual with autism's day for faster gains and greater generalization and maintenance.

Also important when considering treatment priorities are ecocultural variables. This necessitates that treatment goals are developed within an individual's natural settings and with consideration of cultural and psychological diversity. Another important consideration in developing treatment priorities is the least restrictive environment. That is, if a behavior is likely to result in the placement of an individual in a more restrictive educational or community setting, the modification of such behavior would be a treatment priority. Individuals with autism should have the opportunity to engage in and have access to the same basic privileges as his or her respective peers, and the overarching goal of treatment is to achieve this level of equality.

Short Biography

Dr. Darold Treffert is the world's leading authority on the autistic savant syndrome – a term he coined. He has been studying savant syndrome since he met his first savant in 1962, when he developed a children's unit at a hospital in Wisconsin, USA. He is a clinical professor in the Department of Psychiatry at the University of Wisconsin and on the staff of the Behavioral Health Department of St. Agnes Hospital in Fond du Lac, Wisconsin. He maintains a very active web site on savant syndrome at www.savantsyndrome.com through the Wisconsin Medical Society. He is also the author of *Extraordinary People: Understanding Savant Syndrome* (1989) – the first comprehensive book on the condition – and *Islands of Genius: The Bountiful Mind of the Autistic, Acquired and Sudden Savant* (2010). He

was a consultant on the movie, *Rain Man*, in which Dustin Hoffman won an Oscar for his portrayal of an autistic savant.

Dr. Treffert's work has appeared in numerous publications, including *Time*, *People*, *Newsweek*, *USA Today* and *Scientific American*, and he has participated in many documentaries on savant syndrome and autistic disorder. He also has over 50 articles in professional journals. He has been listed in *The Best Doctors in America*, by peer selection, beginning in 1979.

Definition

Trexan or naltrexone is an opiate antagonist used as an adjunct in the treatment of opioid dependence. It became of interest in the 1970s and

1980s as a potential treatment for autism based on the potential role of the endogenous opioid system in autism. There have been several small studies using naltrexone in children with autism. These studies indicate that the medication is generally well tolerated but did not rarely shown to be beneficial for any outcome measured. Outcomes that have been of the interest in these studies include an improved communication, decreased self-injurious behavior, and decreased hyperactivity. The adverse effects of naltrexone include loss of energy, drowsiness, and dizziness.

Description

The social challenges that children with autism experience are pervasive and lifelong. With direct intervention, children with autism can acquire the tools necessary for interacting with others. Many researchers have documented the beneficial effects of teaching social skills to children with autism.

Children with autism experience specific social challenges that are different from children with other developmental disabilities, such as understanding emotions and how to recognize and communicate feelings, knowing how to start and maintain interactions appropriately, and understanding other people's perspectives. Because of their unique challenges, many of the tools available for assessing social skills do not address the level of detail needed for generating program plans for children with autism. In order to teach social skills, we need to determine what each child's individual needs are in order to monitor the effectiveness of teaching plans.

The TSSA is designed for children ages 6–12 years who have basic reading skills at the first grade level. It is criterion-based and assesses knowledge and skills in three areas: (a) cognitive, (b) behavioral, and (c) affective. The *cognitive* areas assess the child's ability to understand other people's perspectives. The *behavioral* aspects determine the child's ability to initiate and maintain interactions and respond appropriately to other people. The *affective* components evaluate the child's abilities to understand basic and complex emotions.

Four sources of information are incorporated into the assessment: (1) parent report, (2) teacher report, (3) observation, and (4) direct child interaction. The parent information provides descriptions of the child's social skills in home and community settings. The teacher information provides descriptions of social skills in the school setting. Parents and teachers also both rate interfering behaviors exhibited by the child. Finally, the direct child assessment provides additional information of the child's skills as observed during interaction with a clinician.

The information from the various sources should be interpreted in terms of the child's

strengths and challenges. The TSSA provides a sample report that can be used to identify teaching goals for school, home, and clinical settings. The TSSA can be downloaded from the following web page: <http://uwreadilab.com/tools-materials/>.

Historical Background

The Vanderbilt Treatment and Research Institute for Autism Spectrum Disorders (TRIAD) was established within the Department of Pediatrics at Vanderbilt University Medical Center in 1998 by Dr. Wendy Stone. Dr. Stone recognized a need in the community for outreach and intervention services for children with autism. In 2005, TRIAD became a partner with the Vanderbilt Kennedy Center for Research on Human Development in order to continue to develop larger and more integrated autism research, training, and clinical programs.

The TSSA was developed originally by TRIAD autism specialists to address the need for a relatively brief, easy-to-administer tool for evaluating the complex social profiles of children with autism spectrum disorders, identifying strengths and challenges in the social domain, and providing recommendations for intervention planning through individualized goals and specific strategies. Used in-house for many years, the TSSA recently has been updated for use in a variety of settings, including the school and community.

Psychometric Data

There are currently no research studies that provide normative or quantitative information about a child's individual performance on the parent and teacher questionnaires or specific testing items. However, very important and helpful information can be gathered from each section of this assessment that will guide recommendations for treatment interventions.

Clinical Uses

The TSSA does not require specific training or a degree. However, the examiner should have

knowledge about the characteristics of autism as well as communication and social skill development. The intent is that this instrument be administered by special educators, speech pathologists, licensed therapists (e.g., occupational therapist, physical therapist), or school psychologists.

The TSSA is an integrated assessment that provides valuable information about a child's social and behavioral strengths and concerns. The information obtained from each section of the TSSA is meant to be a subjective and qualitative guide about the child's functioning in multiple contexts, including home, school, and the direct assessment setting.

The assessment report should include the following sections: background and referral information, a description of the assessment instrument and the child's participation and effort, interaction style, and interfering behaviors, as well as summaries of parent and teacher reports and direct child interaction, and recommendations for goals and interventions. A guideline for the interpretation and content of each section is specified in the manual.

Definition

A (discrete) trial represents an isolated opportunity for an organism to make a single operant response in the presence of a discriminative stimulus. Each discrete trial must contain three components: an antecedent discriminative stimulus, a response, and a consequence. Successive trials are separated by intertrial intervals during which no discriminative stimuli are presented and operant responses are either precluded or are not reinforced.

Definition

Sedation of intellectually disabled patients, such as autism spectrum disorders (ASD), is often applied before invasive or lengthy surgical procedures (Lim et al. 2018). It is estimated that 30% of patients with intellectual disabilities are uncooperative before receiving general anesthesia (Lim et al. 2018). In order to avoid hard restraints, three general sedatives, midazolam, ketamine, and dexmedetomidine, are utilized to calm ASD patients before receiving general anesthesia (Lim et al. 2018). Recently, physicians began administering triazolam after government restrictions on midazolam use in certain countries. To determine whether triazolam was equally efficacious as midazolam, a study consisting of 97 patients with intellectual disabilities were divided into two groups receiving either midazolam or triazolam. Analysis of cooperation after drug administration showed anesthesia induction without physical restraint was possible in 56.0% of patients in the midazolam group and in 46.8% of patients in the triazolam group ($P = 0.312$) (Lim et al. 2018). Therefore, triazolam is an equivalent alternative for sedating uncooperative patients before receiving general anesthesia. However, sedatives pose

an increased risk of respiratory depression, hypoxia, or pulmonary aspiration (Lim et al. 2018). It is encouraged for clinicians to pursue alternative means for calming ASD patients using family or other close caregivers throughout the pre- and postoperative stages of surgical intervention rather than sedation.

Trichotillomania

Chronic hairpulling

Short Description or Definition

Trichotillomania is characterized by recurrent hairpulling that causes noticeable hair loss and significant distress or impairment. A diagnosis of trichotillomania according to DSM-IV also requires that an individual sometimes experience urges prior to pulling and a sense of pleasure, gratification, or relief after pulling. Individuals who do not report urges prior to and a sense of relief after pulling are generally given a diagnosis

of chronic hairpulling. Inability to report sensory phenomenon is common and developmentally appropriate in younger children; thus, there is a strong probability that these diagnostic criteria will be removed from future diagnostic criteria.

Categorization

Impulse Control Disorder

Epidemiology

Trichotillomania has an estimated lifetime prevalence of roughly 0.6%. However, the estimated lifetime prevalence increases to roughly 3% when preceding urges and pleasure/relief afterward are removed from the diagnostic criteria. The prevalence of trichotillomania in patients with pervasive developmental disorders is consistent with these estimates.

Trichotillomania patients have a high rate of comorbid illnesses, with approximately 82% of adults presenting for treatment experiencing at least one other axis I psychiatric disorder (Woods et al. 2006a). Common comorbidities include depression, anxiety disorders, obsessive-compulsive disorder, substance use disorders, posttraumatic stress disorder, and other body-focused impulse control disorders. Trichotillomania in adults has a strong female predominance and a chronic, waxing and waning course.

Natural History, Prognostic Factors, and Outcomes

Trichotillomania has an average age of onset around 13 years. Longitudinal studies of adults with trichotillomania have demonstrated little improvement in symptoms over time (Keuthen et al. 2001). Longitudinal studies have not been conducted in order to establish the long-term prognosis of children with trichotillomania, although it is clear from adult samples that a majority of trichotillomania cases arise in childhood. Hairpulling in young children (less than

5 years of age) is considered a behavior consistent with developmentally appropriate environmental exploration and is usually self-limited. It is currently unclear how the discovery and implementation of therapies with some evidence of short-term efficacy for treating trichotillomania will affect the long-term prognosis of the illness.

Evaluation and Differential Diagnosis

A proper assessment in a patient with trichotillomania involves getting a detailed history of their hairpulling. When discussing hairpulling behaviors, it is important to discuss (1) antecedent cognitions, behaviors, and feelings prior to pulling, (2) the settings in which pulling occurs, (3) body locations from which pulling occurs, and (4) postpulling behavior. Trichotillomania patients commonly experience emotions such as boredom, tension, and anxiety prior to hairpulling episodes and/or a physical urge to pull. Commonly experienced cognitions prior to hairpulling include beliefs about the inappropriate appearance of certain hairs (gray, coarse, etc.), that hairlines or lengths of hair need to be symmetrical, or that she is unattractive or unlovable because of her appearance. Common postpulling behaviors involve biting, rubbing, or eating the hair. Also, discarding of the hairs in fairly stereotyped ways is the norm. In patients who ingest their own hair, trichobezoars – conglomerations of hair and food that form in the gastrointestinal tract – are of particular concern as they can lead to weight loss, iron deficiency anemia, malabsorption, and even gastrointestinal tract obstructions. Frequently, younger children and individuals with developmental disabilities will have difficulty reporting these feelings. In these cases, having a parent journal the child's hairpulling behaviors can be effective.

Trichotillomania patients also usually have specific places where they pull, i.e., the bedroom or the bathroom. The most common sites of hairpulling are the scalp (73%), eyebrows (56%), eyelashes (53%), pubic region (46%), and legs (15%) (Woods et al. 2006a). Adults with trichotillomania tend to pull from more sites than

children. A physical examination of areas of hairpulling can uncover areas of irritation, follicle damage, and atypical regrowth of hair that are common in patients with trichotillomania. Rating scales such as the Massachusetts General Hospital Hairpulling Scale, a patient self-report form, and the National Institute of Health Trichotillomania Severity Scale, a clinician-rated form, are useful in measuring the severity of trichotillomania symptoms and tracking changes in symptom severity over time.

Treatment

Nonpharmacological behavioral treatments should be regarded as the treatment of choice for both children and adults with trichotillomania. Habit reversal therapy (HRT) is a behavioral therapy designed for the treatment of trichotillomania and tics. HRT is a manualized, behavioral technique that is administered over a period of 2–3 months with a maintenance period for relapse prevention. HRT involves several different components – self-monitoring, awareness training, stimulus control, and competing response training. The self-monitoring component of HRT requires patients to keep records of their hairpulling. Awareness training works to increase patient awareness of hairpulling behaviors and of high-risk situations that increase the risk of hairpulling. Stimulus control employs interventions designed to decrease the opportunities to pull and to intervene or prevent pulling behaviors. Competing response training involves teaching a patient to engage in a physically incompatible behavior with pulling for a set period of time when they feel the urge to pull. In HRT, patients are only permitted to pull after they have engaged in the competing response behaviors.

In three randomized, parallel-group studies, HRT demonstrated superior efficacy compared to wait-list or placebo controls (Ninan et al. 2000; van Minnen et al. 2003; Woods et al. 2006b). HRT also demonstrated superiority to pharmacotherapy with fluoxetine and clomipramine in two of these randomized trials (Ninan et al. 2000; van Minnen et al. 2003).

A meta-analysis demonstrated that in randomized, controlled trials of trichotillomania, HRT has demonstrated superior effect sizes compared to pharmacological agents for trichotillomania (Bloch et al. 2007). Further trials are needed to demonstrate that HRT will maintain efficacy when compared to control conditions that account for the nonspecific aspects of therapy (i.e., supportive psychotherapy and psychoeducation).

The main problem with the use of HRT to treat trichotillomania is the lack of availability of clinicians experienced in this behavioral technique. It is unknown the degree to which HRT efficacy is diminished when it is practiced by clinicians less experienced in HRT and trichotillomania. An online website, stoppingpulling.com, provides many of the common HRT techniques in a self-help format for motivated patients who do not have access to an experienced therapist. Furthermore, many patients with trichotillomania do not experience remission of symptoms with behavioral therapy and thus other treatments are needed. Conducting HRT in patients with developmental or intellectual disability is challenging and remains understudied.

Selective serotonin reuptake inhibitors (SSRI) are the most commonly utilized intervention to treat trichotillomania (Woods et al. 2006a). Initial open-label trials showed improvement over time in trichotillomania patients taking SSRI. However, in four randomized, blinded, placebo-controlled trials, SSRIs have failed to show benefit compared to placebo (Christenson et al. 1991; Dougherty et al. 2006; Streichenwein and Thornby 1995; van Minnen et al. 2003). Meta-analysis which combined the results of the four previously conducted trials similarly failed to show any evidence of an improvement compared to placebo treatment (Bloch et al. 2007). Although there is substantial evidence that pharmacological treatment with SSRI is no more effective than placebo in the treatment of primary hairpulling in trichotillomania patients, these medications still may be quite effective in treating comorbid illness in these patients. Depression, anxiety disorders, and posttraumatic stress disorder are all common comorbidities in trichotillomania patients and have substantial evidence

demonstrating improvements with SSRI pharmacotherapy. When SSRI pharmacotherapy is initiated in a trichotillomania patient, the goal of therapy should be to specifically target comorbid illness that is impairing to the patient, as SSRI pharmacotherapy for primary trichotillomania has little evidence of efficacy.

Clomipramine is a tricyclic antidepressant (TCA) that has been extensively studied in the treatment of trichotillomania. Initial results from a 10-week, randomized, double-blind, crossover study of 13 women which compared clomipramine, a serotonergically selective TCA, to desipramine, a nonselective TCA, demonstrated substantial improvement in trichotillomania patients treated with clomipramine (Swedo et al. 1989). However, most of the patients in this trial experience a relapse in their symptoms after longer-term treatment with clomipramine. Another small, 9-week, randomized, placebo-controlled parallel group study showed some increased improvement of trichotillomania symptoms compared to placebo but not to the level of statistical significance (Ninan et al. 2000). Clomipramine was very poorly tolerated in this study, with 40% of subjects dropping out early due to side effects. Common side effects associated with clomipramine include weight gain, anticholinergic symptoms, and sedation. Meta-analysis of randomized trials with clomipramine suggests modest short-term benefits when compared to control conditions. However, evidence suggests that benefits from clomipramine may be short-lived. Randomized trials have suggested that both SSRIs and clomipramine are inferior to HRT.

A double-blind placebo-controlled trial in 50 adults with trichotillomania demonstrated the efficacy of N-acetylcysteine (NAC), a glutamate-modulating agent with antioxidant properties. Fifty-six percent of the subjects given NAC demonstrated significant improvement at 12 weeks compared with only 16% in the placebo group (Grant et al. 2009). N-acetylcysteine showed statistically significant improvement compared with placebo by 6 weeks of treatment. There are no published reports of the use of NAC to treat childhood TTM. However, NAC has been used safely with minimal side effects in the

treatment of acetaminophen overdose in children. N-acetylcysteine doses used to treat acetaminophen overdose are orders of magnitude higher than the 2,400 mg/day suggested for TTM. Possible side effects of NAC include nausea, flatulence, and asthma exacerbation. NAC is available as an over-the-counter supplement for a cost of \$5–15 a month.

A randomized, double-blind, placebo-controlled trial of 25 adults with trichotillomania has also demonstrated the efficacy of olanzapine. Eighty-five percent of subjects receiving olanzapine reported significant improvement compared to 17% in the placebo group after 12 weeks of treatment (Van Ameringen et al. 2006). Olanzapine also demonstrated efficacy on primary measures of trichotillomania in the trial. Because of the significant adverse effects associated with olanzapine such as weight gain, sedation, and metabolic syndromes, even if effective, olanzapine is unlikely to be a first-line treatment for trichotillomania. Case series and case reports have suggested the efficacy of other antipsychotics; however, none have been studied in randomized controlled trials. Most other antipsychotic agents also share a similar side effect profile to olanzapine.

Case report level data suggests the possible efficacy of other pharmacological agents such as riluzole, topiramate, and naltrexone. Skepticism is warranted when viewing the likely efficacy of any treatment of trichotillomania studied in an unblinded, uncontrolled fashion. Many patients with trichotillomania improve over the short term regardless of treatment after presenting for initial treatment. Greater familiarity and psychoeducation about the disorder, meeting other individuals with the disorder, supportive clinicians, and engaging in any active intervention against the disorder are all powerful forces toward patient improvement. These aspects of treatment along with the waxing and waning course of trichotillomania make it difficult to assess efficacy in uncontrolled trials.

Support groups can also be very helpful for treatment for trichotillomania. The Trichotillomania Learning Center based in Santa Cruz, California, can be quite helpful in providing treatment

referrals and support to individuals experiencing trichotillomania. Often times, hearing other individuals' stories, coping mechanisms, and strategies for trichotillomania can be quite helpful in living with and overcoming this illness. The Trichotillomania Learning Center can be contacted through their website at www.trich.org.

Definition

A review of the progress of a student receiving special education services must be conducted at least every 3 years, or more frequently if requested, by the school's Individual Education Planning (IEP) team in order to determine whether the student continues to be eligible for special education services. If, at that time, the IEP team determines that additional information is needed to make this determination, a triennial evaluation will be conducted. The triennial evaluation typically consists of the use of a combination of formal and informal assessment data by a number of professionals within the school

system. Written parental consent must be provided before the evaluations can be completed. For people with Autism Spectrum Disorders (ASD), a comprehensive assessment typically evaluates functioning in a number of areas including cognition, communication, academic achievement, and social-emotional and behavioral development. As part of the triennial review process, assessments are completed in specific areas of concerns. This may include psychological, educational, speech and language, occupational therapy, or physical therapy evaluations by school professionals.

One of the older (first-generation) neuroleptics of the phenothiazine group. This agent has been used most widely in the treatment of schizophrenia and less frequently for other conditions, e.g., Alzheimer's. This agent was occasionally used in the past for treatment of agitation/stereotyped movements in autism. With other agents in this class, it impacts various systems as with other agents in this group; side effects can include movement problems (including tardive dyskinesia). It may also lower the seizure threshold (a particular issue for individuals with autism and seizures). Its primary neurochemical action to be blockade of dopamine D₁ and D₂ receptors in the brain. In autism, the use of this, and similar first-generation neuroleptics, has largely been replaced by the newer "second-generation" (atypical) neuroleptics, e.g., risperidone.

Trust

Kyle Lanning

Definition

In General

A trust is a financial arrangement whereby one person, the trustee, holds property (usually in the form of money) for the benefit of another person, the beneficiary. The person who establishes the trust and whose property is held in the trust is called the settlor. The trustee has legal title to the trust property (also known as the "corpus" of the trust) which allows him to invest the money as a prudent investor would. Over the years, specialized trusts emerged to fit the unique needs of individuals and they currently number in the hundreds. Trusts are particularly useful for ensuring responsible inheritance management, avoiding certain estate and gift taxes and preventing the need for a guardian in the case of incapacity.

To illustrate the basic formulation and function of a trust, let us assume that A and B are the parents of a child, C, diagnosed with an ASD. In order to assure that C is financially supported, either during their lifetime or after their death,

A and B set up a trust through trust company T.C., Inc. wherein an employee of T.C., Inc. will be charged with dealing with the day-to-day management of the trust. A and B then transfer \$1 million into the trust and the trustee; T.O. is bound by the trust document to manage and distribute the money for the sole benefit of C, the beneficiary of the trust.

Important Considerations and Financial Planning

Because a trust is a legal agreement that represents an understanding of a financial arrangement, it is usually (and, in some jurisdictions, required to be) in written form. Thus, the settlor may customize the trust to meet his or her individual needs. Using our example from earlier, A and B can enter a provision into the trust agreement that requires the trustee to distribute money only to pay for the expenses of C that are a direct result of their ASD treatment.

Trusts are an ideal mechanism for protecting assets. First, trust agreements can be structured (most commonly through the inclusion of a so-called spendthrift clause) to create discretionary trusts that shelter the trust assets from creditors. In a discretionary trust, the settlor can postpone and delegate to the trustee the decision of to whom to make distributions, in what amounts, and, more importantly, when. Say, for example, that C incurs a large amount of debt and C's creditors wish to go after the money in the trust that A and B set up for C. A spendthrift clause prohibits the creditor from satisfying the debt from the trust assets because the trustee has the sole authority to distribute the assets.

Trustee

Martyna Smielewska
Quinnipiac University School of Law, Hamden,
CT, USA

Definition

A trustee is a person or entity who holds the assets of a trust for the benefit of a beneficiary. A person who becomes a trustee is granted legal title of a trust and is responsible for managing and controlling all trust assets for the benefit of the beneficiary.

Serving the Role of Trustee

In order to become a trustee, a person must be competent and of legal age. Anyone with the ability to own and transfer property can serve the role of trustee. Once named a trustee, a person must be identified as such by the trust document and the trustee must formally accept the role. Depending on the state, a trustee may be required to take a sworn oath of office and/or post a bond in order to accept the role.

Trustee Duties and Obligations

A trustee's key responsibility involves controlling and protecting the trust. In administering the trust, the trustee must exercise the highest degree of care and he/she has a duty of loyalty to the trust and its beneficiary. The trustee must act in good faith and avoid any conflicts of interest. The trustee must follow any instructions provided by the person (s) who established the trust. The trustee must also exercise great care in financial transactions involving the trust. All transactions must be accurately recorded by the trustee and accounting must be provided to the beneficiary.

Multiple Trustees

There can be more than one person acting as trustee of a trust. If there is more than one trustee, all designated trustees must make joint decisions regarding the trust. Some states require all trustees to be in agreement before any decision related to the trust is made. Other states require only a majority of the trustees to agree on a decision.

Compensation of Trustees

A trust may or may not explicitly state whether a trustee is entitled to compensation. In cases where the trust is silent on the issue of compensation, many states have laws which set forth that a trustee is entitled to some compensation.

Definition

One of the amino acids (essential building blocks of proteins). Tryptophan is found in many dietary products and is a dietary precursor of a number of compounds including serotonin, melatonin, niacin, and others. Tryptophan is available in health food stores as a dietary supplement and has been advocated as an aid for sleep, although research data are mixed on this point. Its main relevance to psychiatry in general (and to autism in particular) has to do with its relationship to serotonin (both in autism and in depression).

Tuberous Sclerosis Alliance

Jo Anne Nakagawa¹ and Sarah Spence²

¹Tuberous Sclerosis Alliance, Silver Spring, MD, USA

²Department of Neurology, Children's Hospital Boston Harvard Medical School, Boston, MA, USA

Major Areas or Mission Statement

In 1974, four mothers of children diagnosed with Tuberous Sclerosis Complex (TSC) formed the Tuberous Sclerosis Alliance (TS Alliance) to provide fellowship, generate awareness, pursue knowledge, and provide hope to those who shared the common bond of TSC. Today, the TS Alliance has grown to almost 1,000 active members with

over 10,000 on its mailing list. It is the only national voluntary health organization dedicated to finding a cure for TSC while improving the lives of those affected through the following activities:

- The stimulation and sponsorship of research into the diagnosis, cause, management, and cure of TSC, a genetic disorder that can affect multiple organ systems
- The development of programs providing individuals with TSC and their families access to support services, resource information, and health care professionals engaged in the diagnosis, treatment, and management of TSC
- The development and implementation of public and professional programs designed to heighten awareness of TSC, thereby prompting early, accurate diagnosis and effective treatment

Landmark Contributions

In the quest to find a cure for TSC, the TS Alliance has contributed more than \$15 million to fund significant scientific breakthroughs. TS Alliance-sponsored research helped to:

- Identify two genes that cause TSC
1993: TSC2 gene on chromosome 16 is identified by a European consortium.
1997: TSC1 gene on chromosome 9 is identified by an International Consortium.
- Develop a genetic test
2002: Dr. Vicky Whittemore at TS Alliance facilitated the transfer of clinical genetic testing from two academic centers (Dr. Katherine Sims at Massachusetts General Hospital and Dr. Hope Northrup at Baylor University in Houston) to Athena Diagnostics, a fee-for-service commercial laboratory. Dr. Northrup helped Athena develop the molecular diagnostic tests for TSC1 and TSC2.
- Initiate the first clinical trial with sirolimus (Rapamune[®]), an FDA-approved drug that

showed promise of meaningful treatment. The trial was expanded into a Phase II, multicenter study co-funded by the National Cancer Institute at the National Institutes of Health. A Phase II Multi-Center Study of Rapamycin for Treating Kidney Angiomyolipomas in TSC or LAM (*Lymphangioliomyomatosis*).

Major Activities

TS Alliance Grants Program: Active since 1984, the TS Alliance has raised funds and administered a grants program to support basic, translational, and clinical research. The TS Alliance encourages the researchers to share information and resources, thus expediting research results and their translation into improved clinical care of individuals with TSC. Grants include postdoctoral fellowship awards as well as principal investigator support for scientists studying TSC and autism. For more information about the TS Alliance Grants Program go to <http://www.tsalliance.org/pages.aspx?content=24>.

In 2006 launched the TSC Natural History Database, a web-based, password-protected central research repository of information about individuals with TSC that includes demographics, genotypes, conditions affecting various organs in the human body, diagnostic and follow-up tests, and treatments. This project is intended to gather information over a participant's lifetime to ultimately improve the care of those affected by TSC, by:

1. Identifying cohorts of adults and children with TSC for future clinical studies and/or clinical trials for treatment of epilepsy, autism, tumor growth, and other manifestations of TSC
2. Improving the understanding of the progression of TSC over an individual's life span
3. Serving as a resource that will hasten the discovery of new treatments and therapies for individuals with TSC and for other causes of epilepsy, autism, cancer, and heart and lung disease

In 2010 launched the TSC Drug Screening Program to support pre-clinical development and testing of new therapies related to neurological and neurocognitive symptoms associated with TSC. TS Alliance is funding research for the steps between compound identification and testing for efficacy in human clinical trials in order to accelerate the development of a potential therapeutic agent for individuals with neurocognitive symptoms associated with TSC.

Short Description or Definition

Tuberous Sclerosis Complex (TSC) is a rare neurogenetic disorder characterized by abnormalities in multiple systems including brain, skin, eyes, heart, lungs, and kidneys (Crino et al. 2006). It is one of the single gene disorders that has been most closely associated with autism spectrum disorders (ASD) and many researchers believe that it can be a good model for understanding the pathophysiology of ASD (Tsai and Sahin 2011).

TSC is caused by mutations in one of two genes (*TSC1* or *TSC2*) which result in the development of benign tumors (hamartomas) in many organs. These gene mutations can either be inherited in an autosomal dominant fashion or occur de novo. They are known to disrupt a key signaling pathway involved in cell size regulation and therefore allow for abnormal cell growth in a number of different systems. Most relevant to ASD are lesions in the brain. The most common lesions are cortical tubers, nests of giant cells, which can cause seizures and are posited to be associated with the cognitive, learning, and behavioral problems (including ASD) that are commonly seen in this disorder. Subependymal giant cell astrocytomas (SEGAs) are so-called benign tumors in the brain that can lead to significant morbidity. Other organ system involvement includes a variety of lesions on the skin as well as fingernails and teeth along with hamartomatous growths in the retina, heart, kidneys, and lungs. Clinical expression and outcome is highly

variable and largely dependent on the specific manifestations of the disorder in a given patient.

Categorization

TSC is categorized as a rare neurogenetic disorder because it is known to be caused by specific gene mutations. It is also considered a neurocutaneous disorder because individuals with TSC have findings both on the skin and in the brain.

Diagnosis is made according to the presence of clinical features (major and minor) (Roach et al. 1998) and can be confirmed by gene mutation analysis.

Major features include findings in the following systems:

- Brain (cortical tuber, subependymal nodule, subependymal giant cell astrocytoma)
- Skin or nails (facial angiofibromas, three or more hypopigmented macules or ash leaf spots, presence of a shagreen patch or a connective tissue nevus, nontraumatic ungula or periungual fibroma)
- Eye (Multiple retinal nodular hamartomas)
- Heart (Cardiac rhabdomyoma)
- Lungs (Lymphangioleiomyomatosis/LAM)
- Kidneys (Renal angiomyolipoma)

Minor features include findings in multiple systems: pits in dental enamel, hamartomatous rectal polyps, bone cysts, cerebral white-matter "migration tracts," gingival fibromas, nonrenal hamartoma, retinal achromic patch, "confetti" skin lesions, multiple renal cysts.

Epidemiology

TSC is considered a rare disorder with prevalence estimated at 1 in 6000. There are up to 40,000 individuals with TSC in the US and one to two million worldwide. There are no known risk factors according to gender, ethnic, or racial groups (NINDS fact sheet).

ASD occurs in up to 40% of individuals with TSC. However, TSC is a relatively rare cause of

ASD with most studies reporting only 1–3% of large autism samples having TSC. Despite much research, the exact factors associated with increased risk of developing ASD in individuals with TSC are still not known.

Natural History, Prognostic Factors, Outcomes

Some cases of TSC are diagnosed very early in life (Datta et al. 2008). The presence of a cardiac rhabdomyoma may even be picked up on fetal ultrasound allowing for diagnosis in the newborn period. Early onset seizures called infantile spasms (IS) are often associated with TSC and careful physical examination and brain imaging can lead to a diagnosis in the first year of life. However, in milder cases, the disorder is often not diagnosed until the skin manifestations arise in later childhood and/or behavioral and learning deficits become more obvious.

This potential for early diagnosis may be especially important for the development of ASD. There are currently intensive research efforts attempting to discover the specific risk factors for ASD and other neurobehavioral outcomes with the idea that we might be able to develop preventative strategies.

TSC is a lifelong disorder and clinical manifestations can change over time. It is crucial that patients have long-term follow-up with providers familiar with the myriad of symptoms associated with the disorder.

Prognosis is extremely variable and dependent on the manifestation of the disorder in the individual patient. Even within the same family (with the same genetic mutation), there are widely variable presentations. For instance, some individuals with TSC only have isolated skin lesions. Alternatively, in other patients, severe renal disease can result in kidney failure, while others may be affected with severe epilepsy, intellectual disability and autism.

Why some individuals with TSC develop ASD is still unknown, but various researchers have suggested that risk factors include worsened seizures, intellectual disability, more tuber burden

(either numbers or volume), or even specific location of tubers in the temporal lobe and/or cerebellum. And more recent data suggests that the neurocognitive phenotype in TSC may be related to subtle abnormalities in the white matter. These findings are unrelated to tuber burden and more suggestive of the idea of aberrant connectivity in the brain, a leading theory for the pathogenesis of ASD (Tsai and Sahin 2011).

Clinical Expression and Pathophysiology

As mentioned, the clinical expression of this disorder is extremely heterogeneous and depends on the burden of lesions in different organ systems (Tuberous Sclerosis Alliance website).

CNS symptoms include seizures often manifesting early in life as infantile spasms. Early and aggressive management of this epilepsy syndrome is important because uncontrolled spasms have been associated with poor neurodevelopmental outcomes. Later seizures can manifest as complex partial epilepsy of differing severity. Some individuals suffer from Lennox–Gastaut Syndrome, a severe epileptic condition associated with multiple seizure types, intellectual disability, and a characteristic EEG pattern of slow spike and wave SEGAs tend to occur during childhood (peak incidence ~9 years of age) and are often associated with signs of increased intracranial pressure (headaches, vomiting). The neurobehavioral expression of TSC ranges from mild learning difficulties or ADHD to severe intellectual disability and autism.

Typical skin findings including hypopigmented macules, facial angiofibromas, and periungual or subungual fibromas are not usually associated with significant morbidity. Whereas nail findings are rare to see in children, facial angiofibromas are not usually present at birth but can appear in early childhood.

Most cardiac rhabdomyomas are completely asymptomatic. However, large tumors in infants can be the cause of congestive heart failure and arrhythmias. These tend to regress in size over time and should be followed regularly with cardiac echo and EKG until they have disappeared or

stabilized in size. As mentioned, with continued improvements in fetal ultrasound, these tumors are now being diagnosed prenatally which allows for much earlier diagnosis of TSC.

The two most common kidney lesions are benign renal angiomyolipomas and cysts, both of which can be asymptomatic or cause destruction of kidney tissue over time. The major morbidity is secondary to bleeding. Other lesions such as malignant angiomyolipoma, oncocytomas, and renal cell carcinoma are rare but can occur. Renal imaging at routine intervals is essential.

Lung involvement most commonly involves lymphangioleiomyomatosis (LAM) which occurs exclusively in women and usually appears after age 20. Significant pathology is associated with breathing difficulties including shortness of breath or coughing or even spontaneous pneumothorax (collapsed lung).

Eye involvement involves hamartomas which appear as flat opaque lesions or as multinodular “mulberry” lesions in the retina. These lesions are usually asymptomatic but serious vision problems from bleeding or retinal detachment have been reported.

Because of intense research efforts, much is now known about the pathophysiology of this disorder. The genes responsible for the disorder (*TSC1* and *TSC2*) code for the proteins hamartin and tuberlin. These two proteins together are involved in regulating the mTOR complex which is part of a key signaling pathway controlling protein synthesis and cell size. Mutations in one or the other gene with subsequent reduction of protein will result in overactivity of the mTOR complex and uncontrolled protein synthesis and cell growth (Tsai and Sahin 2011).

Evaluation and Differential Diagnosis

Evaluation involves a thorough physical examination looking for skin, nail, and tooth findings. An ultraviolet light (called a Wood’s lamp) is often needed to identify the hypopigmented macules, especially in individuals with light skin. Imaging of the brain with MRI is necessary to identify the cortical tubers as well as the presence

of subependymal nodules or SEGA. Because of the frequent comorbid neurobehavioral problems, it has been recommended that all children with TSC undergo thorough behavioral and cognitive assessments (de Vries et al. 2005).

For non-CNS disease, the evaluation involves a number of different specialists. Ophthalmological exam can reveal the retinal changes. Renal ultrasound is recommended at time of diagnosis and at regular follow-up intervals to identify and follow angiomyolipomas. Similarly, echocardiogram and EKG are essential to identify the cardiac rhabdomyomas and to screen for any cardiac arrhythmias. Recent research has shown that many women with TSC have minor, usually asymptomatic lung involvement which can be identified through chest CT. It is currently recommended that women be screened initially in adolescence or at the time of diagnosis for older women.

Differential diagnosis really depends on the signs and symptoms exhibited by the individual. Unfortunately, most manifestations of TSC are not specific when they occur in isolation and thus it is the constellation of symptoms that will steer the clinician toward this diagnosis. Neurobehavioral problems (ASD, intellectual disability, and learning deficits) can have a number of different etiologies, so practitioners need to be aware of the possibility of TSC and look for other signs. Likewise, infantile spasms can be associated with other neurogenetic conditions, structural brain lesions such as focal cortical dysplasias, metabolic disorders, and can even be idiopathic (West Syndrome). However, when seen in a baby with hypopigmented macules and/or tubers on MRI the diagnosis is evident. There are a few signs that are more pathognomonic of the disorder such as the cardiac rhabdomyomas and facial angiofibromas. But the eye, renal, and lung involvement can be sporadic or associated with other diseases.

Treatment

The majority of treatments are aimed at specific symptoms associated with the disorder, but as we

understand more about the pathophysiology of TSC, there is intensifying interest in discovering treatments that specifically target the molecular pathways underlying the condition.

Currently CNS manifestations are treated with a wide variety of approaches (Tuberous Sclerosis Alliance website). Seizures are typically treated with anticonvulsant medications. Infantile spasms associated with TSC are particularly sensitive to vigabatrin. A number of other anticonvulsant medications are used for seizures in children and adults. Vagal nerve stimulation, special diets, and even focal resection epilepsy surgery have also been shown to be effective. The neurobehavioral manifestations including autism are treated with typical behavioral interventions. It is important to note that there are no current data suggesting that these treatments are any more or less effective for the ASD, intellectual, and learning deficits in patient with TSC than in other patients.

Facial angiofibromas can be treated with laser therapy. Renal angiomyolipomas can be surgically resected or treated with embolization procedures that are tissue sparing. Heart lesions and eye lesions usually do not need treatment.

The most exciting prospect in the investigation of new treatment opportunities involves the study of specific molecular compounds designed to impact the signaling pathway known to underlie this disorder. Exciting animal model work has shown that rapamycin (an mTOR inhibitor) can actually prevent the development of epilepsy in mice (Meikle et al. 2007; Zeng et al. 2008). Similarly the neurobehavioral or learning deficits have been reversed in another mouse model (Ehninger et al. 2008). Everolimus has recently received FDA approval for treatment of the SEGAs that are not amenable to surgical resection as well as angiomyolipomas. There are currently clinical trials examining the neurobehavioral effects of this class of medication in humans.

Turkey and Autism

Historical Background

In Turkey, the earlier work with autism has been limited to academic centers in three major cities of Istanbul, Ankara, and Izmir, where the major medical schools were. The first medical center

dedicated to autism was established in 1989 at the Ankara University also where the first department of child psychiatry had been founded by Dr Mualla Ozturk in 1973. Drs Atalay Yörükoğlu in Ankara and Rıdvan Cebiroğlu in Istanbul were also among the academic leaders who clinically utilized the concept of autism as described by Leo Kanner. The DSM criteria after the publication of the DSM III in 1980 were quickly accepted in Turkey and became part of the standard evaluations.

Turkey currently hosts more than 30 university departments of child psychiatry and two state training hospitals with Child Psychiatry Departments that provide diagnosis and some of the treatment services for autism.

The common misperception of the association between autism and cold, distant, over-intellectual mothering with high socioeconomic status was prevalent until the late 1990s, despite the medical model in the academic centers. However, in parallel to the proliferation of the national and worldwide research into the etiology and pathogenesis, autism is now almost unanimously considered as a neurobiologically based disorder of social emotional development evident in social, behavioral, and communication domains by the professionals from diverse backgrounds (from special education to genetics to child psychiatry to psychology). Currently, studies conducted with families and teachers of children with autism show that autism remains to be perceived as an “abnormality” and to be stigmatized.

In Turkey, legislative efforts to meet the educational needs of individuals with disabilities date back to 1952 (Birkan 2007). Until 1995, children with autism received education no different than designed for those with intellectual disabilities. In 1999, following the Ministry of Education’s project for “Autistic Children’s Education (OCEP)” and its implementation in 2000 for children between the ages of 3 and 15, local counseling centers and educational units for children with autism were established (http://mevzuat.meb.gov.tr/html/2567_0.html, 2004). The aim was defined as to set the standards of service to individuals with autism, in accordance with the 19 items of the Charter of Rights for Persons

with Autism presented at the 4th Autism-Europe Congress, Den Haag, May 10, 1992 (<http://www.autismeurope.org/files/files/ae-eypd-edu-final-2-eng.pdf>).

Since the beginning of 1990s, numerous foundations and societies have been formed related to autism, especially with the aims of organizing and providing special educational services that were needed. These include but are not limited to Ilgi, IZEV, TODEV, OYAD, ODER, and TOHU-M. The Autism Platform that brings together these entities has worked in the lobbying, advocacy, and public communication efforts in order to raise awareness and support infrastructural work (Darica et al. 1992).

Most of these foundations and societies have focused their work on providing counseling, guidance, referral, support, special education, education about autism, and related services to families with autism.

The shortage of adequately trained professionals to provide the special education services is a main challenge in meeting the children’s special educational needs. Currently, there are more than thirty universities with departments of Special Education, although, a small number of them have a focus on autism.

Legal Issues, Mandates for Service

The new legislative studies on disabilities began in the second half of 1990s, after a long interval since the initial legislative efforts in 1950s. In 1997, an official position in the government was declared for the administration of the services for the disabled. In 2005, the first law, briefly referred to as “The Law of the Disabled” (Law Nr: 5378), was passed (Birkan 2007; Özgökçeler and Alper 2010). According to this law, individuals with disabilities have access not only to the services to meet their constitutional and international rights but also access to certain services and accommodations commensurate with their disabilities. According to this law, the state is mandated to provide reimbursement to the family of the child with autism for child care as well as support for the child’s special educational needs. The state is also obliged to

create job opportunities for all individuals with disabilities. Early diagnosis and prevention services were also mandated by this law. Although recent major amendments were made in 2012, the law continues to lack regulations regarding vocational training opportunities and employment opportunities both in the private sector as well as the public sector (<http://www.mevzuat.gov.tr/MevzuatMetin/1.5.5378.pdf>).

Overview of Current Treatments and Centers

After the first center for the education of children with autism (OCEM) was established in 1999, there has been a rapid increase in the number of OCEMs throughout the country. An OCEM can either be independent or within the body of a mainstream public school as a special class. Depending on their developmental level and social adjustment, children with autism can also be inclusion students within mainstream classrooms (Aksüt et al. 2000).

Children with autism are also entitled to receive special education and rehabilitation services provided or reimbursed by the state, although the number of hours designated (8 h per month, 2013) for such services is far from sufficient (Yıldırım 2007). The type of the services offered to each child is determined by the RAM, described in an Individualized Education Plan (BEP) (Alpaytaç 2009).

There are currently 49 OCEMs in 28 cities in Turkey. As of 2012, the number of children receiving educational services at these centers was 2,066. As of 2012, in grades 1 through 8, the number of children with autism who are inclusion students is 1,537, and the number of children who are enrolled in a “special class” is 2,022. The proportion of children with autism is quite small if we consider that at 1,605 “educational centers” across the country, at primary education level, 241,746 children with a variety of intellectual disabilities are served (Aksüt 2001).

Unfortunately, special educational services are limited beyond the 8th grade for children with autism.

The number of Vocational Training Centers for Autistic Children was 14 in 2012.

Besides these government-supported services, the families of children with autism and the foundations and societies working with autism assume an active role in introducing and educating the parents on different modes of education and treatment services and disseminating the knowledge to the professionals and the families (such as the web portal by TOHUM foundation prepared based on PCDI method at the address <http://www.tohumotizmportali.org/>).

Overview of Research Directions

The epidemiological facts of autism in Turkey are roughly estimated by the estimates of the WHO, that is, one in 250. An epidemiological research for identifying the prevalence of autism in Turkey is urgently warranted for better planning of the services and allocation of the resources.

Based on the 1/250 ratio, we can assume that there should be 271,000 individuals with autism in Turkey, 81,000 of whom between the ages of 0 and 14. Considering that autism does not only affect the individual but also their families, their doctors and caregivers, as well as their educators, it would be a close approximation to assume that autism is a part of 1,626,000 individuals’ lives; 567,000 in the 0–14 age group.

There are a number of publications from the ongoing research in pharmacology, genetics, and neuroimaging of autism in Turkey. Many studies on the phenomenology and clinical observations of autism have also been published. However, there is a continued need for epidemiological studies for an accurate estimate of the prevalence of autism in Turkey. As is the case for the rest of the world, early identification and intervention studies remain as major needs.

Social Policy and Training

A collaborative research by the State Planning Organization (DPT) and Turkish Scientific Research Council (TUBITAK) in 2002 revealed

that individuals with disabilities are facing great social disadvantages and experiencing the practical, everyday aspects of this social inequality.

Awareness studies and campaigns have been instrumental in making autism a part of the daily language as well as in increasing the parental sensitivity to social emotional development.

A recent event during the writing of this item was a general meeting organized by the Ministry of Family and Social Policies in April 2, 2013. In this meeting, the ministry, alongside the foundations and organizations working in the field of autism, generated an action plan which included points regarding increasing the involvement of individuals with autism in the general social environments, increasing education services and opportunities beyond K-8, increasing media coverage on autism to raise awareness, and increasing early identification and intervention resources.

Definition

A genetic condition in girls in which only one of two X chromosomes is present. In this condition, the individual is phenotypically female and is at risk for a range of difficulties. It is named after Henry Turner who described cases in the 1930s. Various forms of Turner's syndrome have been identified. These can include a complete or a partial absence of one X chromosome. In some cases, only some cells are missing the chromosome (mosaic Turner's syndrome). Diagnosis is sometimes made during the pregnancy (e.g., by amniocentesis or sometimes by ultrasound). A karyotype analysis confirms the diagnosis. Various forms of Turner's syndrome have been identified. These can include a complete or a partial absence of the X chromosome.

Physical abnormalities include low-set ears, webbed neck, short stature, and other features. Medical problems include amenorrhea and sterility and heart as well as visual and hearing problems. A substantial minority of cases exhibit cardiac and cardiovascular abnormalities including coarctation of the aorta and a defective aortic valve. Hormonal factors can inhibit skeletal growth. It is common for the fourth finger/toe to be short. Osteoporosis is frequent due to lack of estrogen and can lead to scoliosis. Abnormalities in other areas include problems with the kidneys and thyroid (typically taking the form of hypothyroidism), and there is an increased risk for diabetes. Those with the condition are typically

infertile, but with modern technology, they may be able to have a child following IVF.

Although sometimes associated with intellectual deficiency, Turner's syndrome is more frequently associated with a range of cognitive problems often consistent with the profile of non-verbal learning disability. These problems can be associated with other difficulties, including in adaptive skills and motor areas. Math skills are frequently impacted. There have been some reports of Turner's syndrome co-occurring with autism.

Individuals with the condition can lead active and productive lives. Medical and learning difficulties can present obstacles and should be a focus of intervention.

Twin Studies in Autism

Paul El-Fishawy
State Laboratory, Child Study Center, Yale
University, New Haven, CT, USA

Definition

Before researchers undertake studies aimed at identifying the genetic factors that contribute to a disorder like autism, whose specific causes are largely unknown, it is useful to attempt to determine the balance between genetic and environmental contributors. The reason is that if it were determined that a disorder were caused mainly by environmental factors, then the yield from genetic research might be quite low. Twin studies are one means of estimating the relative contributions of genes and environment to a phenotype.

The study of the rates of disease in twins can help elucidate the extent to which environmental versus genetic factors contribute to a particular disease or syndrome. When twins share the same condition, they are said to be “concordant” for the illness. When they do not share the disorder, they are said to be “discordant” for the disease. By comparing how frequently monozygotic twins are concordant for a disease (the “monozygotic

concordance rate”) with how frequently dizygotic twins are concordant for the same disease (the “dizygotic concordance rate”), one can estimate the degree to which genetic versus environmental factors contribute to disease.

If monozygotic twins are highly concordant for a disease and dizygotic twins significantly less concordant for a disease, this suggests that genetics plays a larger role than environmental factors in causing the illness. The rationale for this is that for each pair of twins, regardless of whether they are monozygotic or dizygotic, environmental factors are held essentially constant – the twin pairs result from the same pregnancy, are most often raised in the same household, and so are thought to be exposed to largely the same environmental factors. Thus, the main variable that could alter the concordance rate is the genetic composition of each twin pair. Since monozygotic twins share identical genetic material and dizygotic twins do not, a high concordance rate for monozygotic twins and a relatively lower one for dizygotic twins suggests each pair of monozygotic twins shares some identical genetic abnormalities that are contributing to their shared disease, while each pair of dizygotic twins, who do not by definition share identical genetic material, do not share identical genetic abnormalities and thus, do not share the same disease. If on the other hand, monozygotic twins have a rate of concordance for a disease that is similar to the rate for dizygotic twins, then environmental factors are likely to be contributing more than genetic factors to the disorder.

Twin studies in autism have shown that monozygotic twins are concordant for autism significantly more frequently than dizygotic twins. One of the most important initial studies conducted by Bailey et al. in England, found that 60% of monozygotic twins studied were concordant for autism compared to none of the dizygotic twins. When the definition of illness was broadened to include Autism Spectrum Disorders (ASDs) and not strictly autism, the concordance rate for monozygotic twins was greater than 90% and the rate for dizygotic twins was only 10%, giving a heritability estimate of approximately 90%. As discussed above, the high monozygotic concordance and the relatively low dizygotic concordance indicates that genetic factors contribute significantly to ASDs.

These findings have generally been corroborated by more recent studies, such as those conducted by Rosenberg et al. and Taniai et al. In these more recent studies, the dizygotic concordance was higher than those reported by Bailey, suggesting that environmental factors play a more significant role than initially calculated. Similarly, one of the most recent twin studies conducted by Hallmayer et al. reported a monozygotic concordance rate of 77%, and a dizygotic concordance rate of 31%. This most recent report provided the lowest estimate to date of the contribution of genes to ASD (~45%). Not surprisingly, the study quickly generated both proponents and detractors. However, when viewed in the broad context, this study, as have all twin studies of ASD to date, supported considerable genetic as well as environmental contributors to ASD.

Definition

Type 2 punishment refers to the removal of reinforcing or preferred stimulus following a behavior. This consequence for a behavior results in a decrease in the future frequency of the

behavior. Across the continuum of least restrictive procedures, Type 2 punishment is considered less aversive than Type 1, or positive punishment procedures. Type 2 punishment, like any punishment procedure, should be employed only after reinforcement-based procedures have failed to be effective. Common types of Type 2 punishment include time-out and response cost procedures.

U.S. Family and Medical Leave Act

Family and Medical Leave Act.

The Family and Medical Leave Act (FMLA) of 1993 is a Federal law which requires employers to provide unpaid leave for employees who have a serious medical condition requiring time off their job or time off to care for a family member. The law was signed into law by President Clinton and came into effect on August 5, 1993.

The Act provides for 12 weeks of unpaid, job-protected leave within a 12-month period for various reasons, including caring for a new child, caring for a seriously ill family member, recovering from the employee's own serious illness, caring for an injured family member who has been in military service, and addressing exigencies which stem from the active deployment of a family member.

The National Defense Authorization Act for Fiscal Year 2010 amends military family leave entitlements under the Family and Medical Leave Act (FMLA) to expand coverage for military caregiver leave. Additionally, the Airline Flight Crew Technical Corrections Act, Public Law 111-119, also modified eligibility requirements for flight crew members.

UCLA Young Autism Project

Definition

The UCLA Young Autism Project (YAP) is an applied behavior analytic intervention model for preschool children diagnosed with autism spectrum disorders. Based on the work of O. Ivar Lovaas, the treatment consists of 40 h per week of intensive one-to-one therapy over a period of 2–3 years, usually beginning when children are under the age of 3½ years.

Historical Background

The UCLA Young Autism Project has its origins in research conducted in the 1960s on the use of operant conditioning in the treatment of children with autism (DeMye et al. 1981). These early studies were quite successful in demonstrating immediate gains in adaptive skills such as language and reductions in problem behavior such as aggression and self-injury, but long-term outcomes were poor, with most children reverting to pretreatment levels of functioning.

The UCLA YAP was initiated by Lovaas in 1970 in an effort to improve outcomes. It differed from previous ABA programs in its focus on young children, delivery of treatment in the home with parental participation, use of a comprehensive curriculum, and recruitment of undergraduates who worked in teams to provide 40 h per week of instruction. In 1987, Lovaas summarized the initial results of this project in a landmark study published in the *Journal of Consulting and Clinical Psychology*, which was later supplemented by a long-term follow-up study of

these same children by McEachin, Smith, and Lovaas (1993). The compelling results reported by Lovaas and colleagues were unprecedented in the early intervention literature and prompted both excitement and heated controversy within the field.

In order to validate his findings, Lovaas recognized the need for replication of the results across multiple studies. Replication projects of the UCLA YAP were instituted at other sites beginning in the 1990s, including Smith, Groen and Wynn (2000) study and the National Institute of Mental Health Multisite Young Autism Project (Cohen et al. 2006; Sallows and Graupner 2005), among other independent replications. Although these studies did not produce outcomes of the magnitude originally reported by Lovaas (1987), they did confirm his primary finding that the UCLA model of early intensive behavioral intervention (EIBI) can be effective in accelerating the development of some children with autism (Smith et al. 2008).

The YAP closed when Lovaas retired from UCLA in 2004, but the intervention model continues to be implemented through the Lovaas Institute for Early Intervention and replication sites.

Rationale or Underlying Theory

According to Smith and Lovaas (1998), the Young Autism Project was designed to address the large discrepancy in learning styles between children on the spectrum and their typically developing peers. While most children learn by exploring and interacting with their environments in novel and creative ways, the idiosyncratic behaviors and restricted interests of children with autism generally prevent them from engaging in this style of learning. Lovaas theorized that a highly intensive intervention was needed to account for these lost learning opportunities and would be most effective if implemented early in the child's life across school, home, and community settings (Smith et al. 2008). The intervention is also designed to maximize success and minimize failures for the child in order to reduce the frustration

and ensuing avoidance behaviors that often accompany typical teaching situations. Ultimately, the YAP aims to construct a functional educational environment that meets the unique needs of children with autism (Smith and Lovaas 1998).

Goals and Objectives

The ultimate goal of the YAP is to maximize behavioral treatment gains for children with autism during most of their waking hours and across all significant environments (Lovaas 1987). By creating educational environments that cater to the specific needs of children on the autism spectrum, the YAP aims to match the learning opportunities available to typically developing children and improve global functioning (Smith and Lovaas 1998).

Treatment Participants

Ideal treatment participants meet criteria for autism as defined in the Diagnostic and Statistical Manual of Mental Disorders (American Psychiatric Association [APA] 1994) and generally begin treatment before the age of 42 months. According to some reports, best outcomes are generally attained by participants who are able to acquire speech early in treatment, while those who have difficulty with this skill tend to demonstrate poorer outcomes.

Treatment Procedures

The treatment, as originally prescribed, calls for an average of 40 h per week of intensive one-to-one behavior therapy over a period of 2–3 years and is conducted in the subject's home, school, and community by a team of therapists and the subject's parents. The treatment is based in reinforcement (operant) theory and relies on shaping behaviors through reinforcement of successive approximations, the use of prompting and fading procedures, and the reduction or reshaping of

aggressive behaviors into more socially acceptable, functional forms of behavior (Smith and Lovaas 1998). Discrimination learning is used to help the child generalize learned skills across other environments.

In the first year of treatment, the primary instructional method is discrete trial teaching, focusing on self-help skills, elementary receptive language skills, simple verbal and nonverbal imitation, and establishing the beginnings of appropriate toy play. Once these skills have been mastered, the second year of treatment is geared toward teaching expressive language skills and interactive play with peers, as well as preparing subjects to enter preschool. Subjects are first taught how to engage in standard preschool activities in the home and are gradually introduced into the school setting over time. Once subjects master these milestones in the second year, the third year of treatment emphasizes general school-based tasks, such as basic reading and writing skills, interactive play with peers, and observational learning (or learning by watching others learn) (Smith and Lovaas 1998). The goal of this gradual introduction to the classroom environment is to ease the transition into kindergarten and ultimately ensure the child's success in a general educational setting.

Efficacy Information

The original UCLA study examined three separate groups: the experimental group and Control Groups 1 and 2. Control Group 1 received 10 h of behavior therapy per week, while those in Control Group 2 received special education services in local public schools without input from or contact with the UCLA project. At follow-up, subjects in the experimental group demonstrated significantly higher educational placements and IQ scores than subjects in either control group. Of the 19 experimental group subjects, 47% ($n = 9$) were eventually determined to be "normally functioning," compared to 2% ($n = 1$) of the control group subjects (Lovaas 1987). A further follow-up was conducted at age 12, and it was found that subjects in the experimental group maintained

these gains and also scored higher than control group subjects on measures of personality and adaptive behavior (McEachin et al. 1993).

Opportunities for replication have been somewhat restricted due to the intensity and duration of the intervention. Of those replication studies that have been completed, all have reported significant gains for children in the experimental condition, although these results have not been of the same magnitude as those of the original study (Howlin et al. 2009). In addition to the feasibility of replication, some aspects of the methodology used by Lovaas have sparked controversy among critics who question the validity of his results (Gresham and MacMillan 1998; Howlin et al. 2009). Many of the replication studies have attempted to address these methodological weaknesses. Despite these issues and the need for further replication, early intensive behavioral interventions based on the UCLA model are widely regarded as highly effective for the treatment of some young children autism (Howlin et al. 2009; Reichow and Wolery 2009).

Outcome Measurement

In the original study (1987), Lovaas incorporated two primary outcome measurements: the subject's posttreatment IQ score and first-grade educational placement, between the ages of 6 and 7 years. The choice of IQ measure was determined according to the subject's developmental level and most frequently included the Wechsler Intelligence Scale for Children-Revised, the Stanford-Binet Intelligence Scale, and the Peabody Picture Vocabulary Test. Information about first-grade placement was assessed by parent report and validated by the educational institution.

Qualifications of Treatment Providers

The clinicians administering the behavioral interventions in the original study (Lovaas 1987) were undergraduate students with superior performance in a course on behavioral treatment, as well as senior staff members with 2 years or

more of experience with the YAP (Smith and Lovaas 1998). All clinicians were trained and supervised by doctoral-level psychologists with many years of experience in treating children with autism.

Definition

A summary of theory and research on the relevance of uncertainty processing to core symptoms of autism spectrum disorder.

Historical Background

Autism spectrum disorder (ASD) is often associated with a difficulty in processing and a lack of preference for uncertainty in the environment. Since the first description of ASD by Leo Kanner, ASD has been associated with a preference for sameness and predictability. Kanner described this cluster of symptoms as “an anxiously obsessive desire for the maintenance of sameness” and explained that “changes of routine, of furniture arrangement, of a pattern, of the order in which every day acts are carried out, can drive him [a child with ASD] to despair” (Kanner 1944, pp. 215). Other early conceptualizations have suggested that individuals with ASD tend to have extremely negative reactions to unexpected events (Baron-Cohen 1989; Dawson and Lewy 1989; Hutt et al. 1964).

Since the first inclusion of autism in the *Diagnostic and Statistical Manual of Mental Disorders* (a classification system for all psychiatric disorders), the diagnostic criteria for autism have always included atypical responses to uncertainty as a core symptom. The *Diagnostic and Statistical Manual of Mental Disorders*, third Edition (DSM-III), the first version to include autism, describes “Bizarre responses to various aspects of the environment, e.g., resistance to change” as a symptom of infantile autism (APA 1980). The Revised DSM-III (DSM-III-R) includes the following symptoms of autistic disorder: “Marked distress over changes in trivial aspects of environment (for example, when a vase is moved from usual position)” and “Unreasonable insistence on following routines in precise detail (for example, insisting that exactly the same route always be followed when shopping)” (APA 1987). The DSM-IV describes “Apparently inflexible adherence to specific, nonfunctional routines or rituals” as a possible symptom of autistic disorder (APA 1994). Most recently, the DSM-5 includes the following as a symptom of ASD: “inflexible adherence to routines, or ritualized patterns of verbal or nonverbal behavior (e.g., extreme distress at small changes, difficulties with transitions, rigid thinking patterns, greeting rituals, need to take same route or eat the same food every day)” (APA 2013).

Current Knowledge

Relations Between Uncertainty Processing and Autism Symptoms and Features

Impairments in processing uncertainty, and impairments in the related construct of prediction, are increasingly being recognized as important features of ASD that are linked to core symptoms and co-occurring conditions associated with ASD. Previous research indicates that children with ASD prefer to engage in predictable or repetitive tasks (Boucher 1977) and demonstrate increased attention to and engagement with objects presented underpredictable versus unpredictable conditions (Ferrara and Hill 1980). Children with ASD also show an exaggerated response to changes in their environment (Kootz et al. 1982) and reduced exploration of novel or unfamiliar environments (Pierce and Courchesne 2001). Individuals with ASD also report that changes in their schedules or transitions are one of the primary sources of stress in their lives (Gillott and Standen 2007).

The two defining features of ASD, impaired processing of social and communicative information and restricted repetitive behaviors (APA 2013), both have relevance to uncertainty processing. First, a preference for sameness and aversion toward uncertainty would undoubtedly impact social functioning in individuals with ASD given the inherent unpredictable nature of social stimuli in the naturalistic environment. The complexity and dynamicity of human interactions make predicting social behavior extremely difficult, even for the most socially skilled individuals. Yet, for individuals with ASD, fundamental deficits in perspective-taking and social attention likely make social stimuli even more unpredictable. Thus, a preference for predictability in ASD, along with pervasive social deficits, may ultimately reduce motivation to attend to and interact with social stimuli in ASD.

In contrast to this pattern of reduced social motivation, individuals with ASD often have intense, specialized, and restricted interests referred to as *circumscribed interests* (APA 2013). These interests are more intense and less flexible than interests in typically developing (TD) children and frequently

interfere with the development of social relationships and participation in functional activities (Klin et al. 2007; Turner-Brown et al. 2011). Interestingly, the most common circumscribed interests in ASD are predictable objects, events, or functions (e.g., machines, mechanical systems, vehicles, computers) (Baron-Cohen and Wheelwright 1999; Turner-Brown et al. 2011). Likewise, for decades it has also been recognized that some individuals with ASD have enhanced skills in certain domains. These so-called islets of abilities (Shah and Frith 1983) typically are in topics related to mathematics, calendar calculations, and visual search tasks (Pring 2005). Typically, what these domains have in common is that they are rule-based and predictable, thereby minimizing ambiguity and uncertainty. More recent evidence also indicates that an intolerance of uncertainty is associated with sensory sensitivity (Neil et al. 2016) and repetitive behaviors in ASD (Vasa et al. 2018).

Therefore, both areas of preserved abilities and impairments in ASD share an affinity for certainty and an aversion of uncertainty. For this reason, understanding uncertainty processing in ASD is likely of prime importance to gain insight into cognitive systems with etiologic relevance to the disorder.

More broadly, two recent theoretical models have suggested that a core deficit in ASD may be related to how individuals with ASD process uncertain events and develop predictions based on these events. The first model, proposed by Sinha et al. (2014), suggests that individuals with ASD have an impaired ability to understand predictive relationships in the environment. According to this model, an inability to effectively develop and test predictive hypotheses results in individuals with ASD living in a constantly unpredictable and uncertain environment. Insistence on sameness and avoidance of social interaction thus minimizes the impact of this deficit. A second theoretical model, developed by Van de Cruys et al. (2014), builds upon the first model by suggesting that impaired predictive coding in ASD is the result of an inability to learn from relevant predictive cues in a dynamic and uncertain environment. According to this model, individuals with ASD are overly attuned to uncertainty in the environment as they

expect every situation to meet very precise predictions based on past events. Thus, they place too much weight on irrelevant violations of their expectations and predictive coding becomes shaped by environmental noise or random variability rather than relevant cues. The authors suggest that this effect is particularly robust in complex and dynamic situations such as social interactions. Accordingly, individuals with ASD may prefer to engage in repetitive and stereotyped behaviors with known contingencies, while avoiding the relative uncertainty of social interactions.

Intolerance of Uncertainty and Anxiety in ASD

Processing uncertainty in the environment is a critical component of learning, and the drive to resolve uncertainty has been proposed to be a principal motivating force for nearly all human behavior (Kagan 1972). The preference for predictability in ASD bears notable resemblance to a construct that has been primarily studied in the context of anxiety disorders referred to as “intolerance of uncertainty” (Rodgers et al. 2012). Individuals with intolerance of uncertainty find uncertain situations stressful and distressing, tend to interpret ambiguous information as threatening, and find it difficult to function in the face of uncertainty (Buhr and Dugas 2009). An intolerance of uncertainty is a characteristic of a range of anxiety disorders, including generalized anxiety disorder (Ladouceur et al. 2000b), obsessive-compulsive disorder (Tolin et al. 2003), and social anxiety disorder. Although the causal relationship between intolerance of uncertainty and anxiety warrants further research, it is clear that intolerance of uncertainty serves as a broad vulnerability factor for anxiety disorders (Carleton 2012). In addition, intolerance of uncertainty is a common intervention target in anxiety disorders, and treatment-related reductions in the intolerance of uncertainty are associated with reduced anxiety in individuals with anxiety disorders (Wilkinson et al. 2011).

As many as 50–75% of individuals with ASD meet criteria for an anxiety disorder (Mosner et al. 2019), and individuals with ASD often meet criteria for multiple anxiety disorders (Simonoff et al. 2008). A growing body of research is focused on understanding intolerance of uncertainty in

autism and has consistently found elevated intolerance of uncertainty in children and adults with autism (Rodgers et al. 2017). There is evidence for strong positive correlations between anxiety and IU in ASD (Boulter et al. 2013; Chamberlain et al. 2013; Wigham et al. 2014) and evidence that intolerance of uncertainty mediates the relationship between anxiety and ASD, suggesting that intolerance of uncertainty may play a causal role in the development of anxiety in ASD (Boulter et al. 2013). However, it remains unclear the extent to which the aversion to uncertainty in ASD is characterized by beliefs that uncertainty necessarily results in negative outcomes as is the case in anxiety disorders (Koerner and Dugas 2006, 2008). Kerns et al. (2014) suggested that distress associated with uncertainty may be an important factor in the development of anxiety in ASD, highlighting that intolerance of uncertainty is an important mechanism contributing to the emergence of anxiety in ASD and an appropriate target for ASD intervention. Boulter et al. (2014) found that intolerance of uncertainty and anxiety were correlated in ASD and that intolerance of uncertainty mediates the ASD-anxiety association (in other words, intolerance of uncertainty may be a causal factor of anxiety in ASD). According to this model, insistence on sameness in ASD may serve as a maladaptive coping strategy aimed at reducing uncertainty and thus anxiety. Additionally, in a group of children with ASD receiving treatment for anxiety, high levels of pretreatment intolerance of uncertainty predicted poorer treatment response (Keefer et al. 2017). Further, in a study designed to validate a new self- and parent-report measure of anxiety in children with ASD using factor analysis, Rodgers et al. (2016) identified four anxiety factors in ASD, one of which was an uncertainty intolerance subscale.

The “insistence on sameness” symptom observed in most individuals with ASD shares many qualities with intolerance of uncertainty. This symptom domain includes repetitive thoughts and actions, behavioral rigidity, a reliance on routines, resistance to change, and obsessive adherence to rituals. Ritualistic behaviors and insistence on sameness in ASD may reflect behaviors that function to minimize uncertainty in the

environment. Additionally, insistence on sameness behaviors in ASD may reflect, at least in part, processes to reduce anxiety in the face of intolerance of uncertainty. Anxiety disorders are characterized by active avoidance of high uncertainty situations to avoid accompanying negative emotions. Outside of the context of ASD, anxiety is modulated by predictability even if the uncertain outcomes do not have aversive consequence (Grupe and Nitschke 2013). Additionally, anxiety is a cause of ritualistic and repetitive behaviors, including benign leg-swinging in typically developing children (Soussignan and Koch 1985) and self-injurious stereotypies in animal model studies (Fox 1986). Across species, there is compelling evidence that ritualistic and repetitive behaviors that manifest under conditions of uncertainty or unpredictability are anxiolytic, serving to elicit calm under conditions of stress (Eilam et al. 2011). In this manner, insistence on sameness and associated ritualistic behaviors in the context of uncertainty may be adaptive responses to anxiety that is prompted by intolerance of uncertainty.

Indeed, anxiety symptoms and disorders are highly prevalent in ASD and anxiety is a common treatment target for individuals with ASD. Further, there appears to be a clear linkage between symptoms related to intolerance of uncertainty and anxiety in ASD. For example, in children with ASD with clinically significant anxiety, Rodgers et al. (2012) found a correlation between anxiety symptoms and insistence on sameness behaviors, but not other ASD symptoms. Similarly, Abramson et al. (2005) reported that children with increased insistence on sameness behaviors were more likely to have parents with anxiety symptoms.

Emotional Regulation in ASD

Although the core features of ASD are in the domains of social communication and restricted and repetitive behaviors, ASD is characterized by broad impairments in affective expression and regulation, including tantrums, aggression, self-injury, anxiety, and irritability (Lecavalier 2006). Emotion regulation is a critical adaptive response that appears to be impaired in ASD, and these

impairments may contribute to the increased rates of internalizing disorders in ASD given that such disorders are themselves characterized by impaired emotion regulation (White et al. 2009). Moreover, emotion regulation impairments in ASD are associated with the overall severity of all core ASD symptoms (Samson et al. 2014) and compromise the quality and quantity of early social interactions (White et al. 2014). Children with ASD frequently display decreased positive and increased negative emotional responses and poor recognition of emotions (Mazefsky et al. 2013). As already discussed, intolerance of uncertainty is a hallmark of anxiety disorders and is an associated feature of a number of ASD characteristics, including insistence on sameness and rigid adherence to routines. Additionally, given that, under conditions of uncertainty, ritualistic and repetitive behaviors may help to reduce anxiety, it may be the case that impaired emotion regulation may similarly be a risk factor for intolerance of uncertainty given impairments with emotion regulation that characterize ASD. In other words, impaired emotion regulation, combined with intolerance of uncertainty, may together potentiate anxiety symptoms that are so commonly observed in ASD. Indeed, there is some emerging evidence that intolerance of uncertainty is associated with emotional dysregulation in ASD, even when controlling for symptoms of anxiety (Vasa et al. 2018).

Treatment Models for Uncertainty Processing

Outside of the context of ASD, most theories of psychosocial interventions for intolerance of uncertainty rely on cognitive strategies, including changing negative assumptions about uncertainty and seeking additional information. Based on a model in which uncertainty is a core deficit in anxiety disorders, Ladouceur and colleagues (2000a) designed a cognitive behavioral treatment for intolerance of uncertainty that addresses the four main components of intolerance of uncertainty. This treatment involved explaining the concept of intolerance of uncertainty; how to recognize, accept, and tolerate uncertainty in adaptive ways; the distinction between real and

imagined negative outcomes; reevaluation of potentially positive beliefs about uncertainty; problem-solving training; and finally, exposure. A randomized controlled trial of adults with anxiety disorders found improvement in intolerance of uncertainty, anxiety symptoms, worry, and depressive symptoms that were maintained at 6- and 12-month posttreatment assessments, with 77% of the sample no longer meeting diagnostic criteria for anxiety disorders at both assessments (Ladouceur et al. 2000a). This treatment model suggests that intolerance of uncertainty and uncertainty processing are amenable to psychosocial intervention.

Although treatment methods that use cognitive strategies to cope with the intolerance of uncertainty in ASD are beginning to be evaluated, it is largely still unknown to what extent these approaches would be beneficial in the ASD population, and which patient characteristics might predict better treatment response. In general, individuals with ASD who have more skilled communication abilities are good candidates for psychosocial interventions (Wyman and Claro 2019), and future clinical trials should evaluate the efficacy of psychosocial interventions in targeting intolerance of uncertainty in ASD. In an initial study in this area, Keefer et al. (2017) examined whether intolerance of uncertainty affected outcomes following cognitive behavioral therapy for anxiety in children with ASD. They found that higher levels of pretreatment intolerance of uncertainty predicted higher anxiety before and after treatment, suggesting that targeting the intolerance of uncertainty may improve outcomes for therapy in youth with ASD. Finally, Rogers and colleagues (2018, 2017) recently developed “Coping with Uncertainty in Everyday Situations for Autism (CUES-A©),” a manualized treatment that targets intolerance of uncertainty in children with ASD. This intervention trains parents to help their children to manage intolerance of uncertainty. A recent initial validation study suggested that the intervention is feasible, acceptable, and valued by families. These results indicate that larger trials are warranted to evaluate the true effectiveness of this intervention.

Behavioral Measures of Uncertainty Processing

Behavioral differences have also been found in terms of responding to uncertainty. Using a task referred to as the “beads task,” which has been well-validated for measuring individual differences in responses to uncertainty (Broome et al. 2007; Ladouceur et al. 1997), adolescents with ASD tend to seek more information in an uncertain context before making a decision relative to controls (Brosnan et al. 2014). However, it may also be important to note that another study involving an adult sample found that the ASD group chose fewer beads (i.e., sought less information) than the control group (Jänsch and Hare 2014), suggesting that adults with ASD may use a “jumping to conclusions” approach (i.e., choosing only one or two beads before making a decision) as a coping strategy for avoiding the experience of uncertainty.

Neurobiological Measures of Uncertainty Processing

There is also emerging evidence from neurobiological studies for atypical uncertainty processing in ASD. For instance, an event-related potential referred to as the “mismatch negativity (MMN)” indexes differences in the processing of unexpected events. Evidence for the MMN response in ASD is somewhat mixed. In individuals with ASD, the MMN response has been found to be reduced (Seri et al. 1999), increased (Ferri et al. 2003; Gomot et al. 2002), and, in some cases, statistically equivalent (Čeponienė et al. 2003; Kemner et al. 1995). In addition, studies of the P3a (an event-related potential response related to novelty processing) has consistently found attenuated P3a responses in children with ASD (Čeponienė et al. 2003; Courchesne et al. 1985, 1994; Dawson et al. 1988; Kemner et al. 1995; Lincoln et al. 1993; Oades et al. 1988), indicating that children with ASD may be impaired in processing unexpected change.

Using a passive functional MRI task examining the processing of unexpected stimuli within a series of predictable stimuli, Gomot et al. (2006) found that children with ASD showed relatively

reduced activation of the left anterior cingulate during the processing of unexpected stimuli. When this study was repeated as an active choice task, Gomot et al. (2008) found that children with ASD showed relatively increased activity in the right superior/middle and inferior frontal gyrus, right precentral gyrus, right postcentral gyrus, left inferior parietal lobule, and left middle frontal gyrus, as well as attenuated activation in the right caudate. Children with ASD were also faster at detecting the unexpected stimulus. When viewed in the light of the findings of Gomot et al. (2006), these results may suggest that children with ASD are able to process uncertain stimuli more effectively when their attention is directed toward it. However, it is important to note that Gomot et al. (2006) did not collect behavioral data and further research in this area is clearly needed in order to support these findings and rule out possible alternate explanations. In particular, attentional or multisensory processing deficits in ASD may explain this pattern of results. In addition, because response times were faster in the ASD group than the control group in this study, the hemodynamic response (as measured by fMRI) may have simply occurred earlier in the ASD group than the control group.

Future Directions

Despite evidence for the high prevalence of intolerance of uncertainty and insistence on sameness in ASD (Lam and Aman 2007; Richler et al. 2007) and evidence that sameness and ritualistic behaviors in ASD significantly contribute to the stress of caregivers and adults with ASD (Boulter et al. 2014; Gabriels et al. 2005; Gillott and Standen 2007), the study of uncertainty processing in ASD is clearly an emerging field. Although intolerance of uncertainty has been studied extensively in individuals with anxiety disorders, the recognition of its relevance to core and associated ASD symptoms is a relatively new topic of inquiry. Although emerging data suggests that intolerance of uncertainty is related to insistence on sameness symptoms, anxiety, and emotion regulation impairments in ASD, research is needed to evaluate the

extent to which the intolerance of uncertainty is associated with other ASD features. For example, intolerance of uncertainty in ASD has been found to be related to sensory sensitivities (Neil et al. 2016), and, together with anxiety, intolerance of uncertainty has been shown to mediate relations between sensory sensitivities and repetitive behaviors in children with ASD (Wigham et al. 2015). Additionally, Vasa et al. (2018) found that the severity of intolerance of uncertainty was related to the magnitude of social communication deficits, repetitive behaviors, and emotion dysregulation in children with ASD *while controlling for anxiety*. This important finding highlights the far-reaching impact of intolerance of uncertainty as it is related to core ASD symptoms. However, the extent to which interventions that target intolerance of uncertainty in ASD also impact the core symptoms of ASD remains to be evaluated.

A better understanding of the role of uncertainty processing in ASD may have important implications for identifying the active ingredients in effective behavioral interventions for ASD. Many empirically validated interventions for ASD are designed to increase predictability and minimize uncertainty, such as applied behavior analysis (ABA). The study of uncertainty processing in ASD may also inform the development of early intervention programs. If the uncertainty of social stimuli decreases their motivational salience, infants and toddlers at risk for ASD may choose to avoid or ignore social stimuli more and more over the course of development, ultimately resulting in greater social and communicative impairments later in life. Consequently, early intervention programs that increase the predictability and consistency of social stimuli may help to prevent children from following this aberrant developmental trajectory. Interventions for ASD may also incorporate a component that directly addresses the elevated levels of intolerance of uncertainty in this population, such as the intervention designed by Rodgers et al. (2017).

Given the transdiagnostic nature of uncertainty processing, it is likely that the lessons learned about cognitive mechanisms of intolerance of uncertainty in other psychiatric disorders, particularly anxiety disorders, may guide research into

intolerance of uncertainty and its treatment in ASD. The evidence highlighting the success of psychosocial treatments in targeting intolerance of uncertainty in anxiety disorders (Ladouceur et al. 2000a) combined with the high rates of anxiety disorders in ASD (Leyfer et al. 2006), suggest that lessons learned from studying and treating intolerance of uncertainty in anxiety disorder may be a promising starting point to more fully investigate intolerance of uncertainty and ultimately develop treatments for intolerance of uncertainty in ASD.

Understanding Parent's Intervention Choices for Their Child with ASD

Definition

Understanding the decisions made by parents when choosing interventions for their child with autism spectrum disorder.

Historical Background

Autism spectrum disorder (ASD) predisposes an individual with a number of core symptoms and comorbid problem behaviors that are well documented but as yet adequately explained. While modern medicine exists to protect, promote, or restore health, the complexities inherent in a neurodevelopmental disorder such as ASD create scientific challenges when seeking to elucidate its biological underpinnings. This lack of

understanding, in turn, leads to clinical challenges in assessment, diagnosis, treatment, and prevention. Currently, there is no universally accepted theory of ASD causation, nor is there a cure. However, the absence of an etiological base has not prevented the establishment of numerous ASD-related interventions, which in number now run into the hundreds. In the medical sense, an intervention exists to either eliminate or reduce a set of target symptoms. Since its establishment as a diagnostic category, formalized in the *Diagnostic and Statistical Manual of Mental Disorders* (Version 3; 1980) by the American Psychiatric Association, ASD interventions have continued being symptomatic and not curative. Of these interventions, many have been shown to be ineffective or are argued to be unethical, unsafe, or else have yet to be evaluated despite their widespread use. As such, there exists no universal standard of care across health professionals, and consequently in many parts of the world, it is the parents who have historically shouldered the responsibility of choosing their child's ASD-related interventions. Though the choices available to parents have increased over the last 50 or so years, the diverse symptomology of their child's disorder means no "one-stop shop" for treatment exists, which further complicates the decisions parents have to make while under pressure to "get it right."

Only 60 years ago the cause of ASD was largely thought to arise from children being raised in emotionally static environments by "refrigerator mothers" whose lack of affection and closeness to their child interfered with attachment and personality development. Consequently, intervention choice was limited to psychoanalytical approaches specifically designed to undo the development damage wrought by parents. In the later part of 1960s and 1970s, the refrigerator mother hypothesis was debunked and put to rest, only to be replaced by another hypothesis that was later to be discredited, the autism/vaccination hypothesis. Not only would it take decades to finally discredit explanations based on the effects of vaccines and other environmental pollutants (e.g., lead), but the biological interventions they gave rise to, such as chelation therapy and secretin supplementation, served only to install parents with false hope and deliver little in

the way of efficacy. By the 1980s, an increasing awareness of the genetic contribution to ASD emerged, though the provision of such knowledge was not immediately translated into new approaches to intervention. In 1987, what has become known as the Lovaas method, or more latterly intensive applied behavioral analysis (iABA) therapy, was described. Though multiple and diverse behavioral approaches to the treatment of ASD had been reported previously, for example, electric shock therapy in the 1950s, the Lovaas approach emphasized early intervention typified by high-intensity treatment regimens delivered one-on-one in clinical settings and then continued by parents at home. While fringe biomedical interventions such as electroconvulsive therapy and medications exist in contemporary clinical practice, the behavioral techniques evolving from the Lovaas method have been the most scrutinized and arguably the most supported by scientific data.

In contemporary times the increasing awareness of ASD has unleashed a multitude of interventions claiming, with or without evidence, to mitigate symptoms or even offering a total cure. Broadly, interventions are classed as biologically based, targeting a specific physiological process that has been found, or hypothesized, to be dysfunctional, or psychologically based, in which the goal is to increase or decrease target behaviors through established conditioning techniques. In clinical practice the most common biological treatments are prescription medicines, where different families of drugs generally focus on a specific symptom or comorbid condition, as opposed to targeting ASD in the broader sense. In the USA, for example, the prescription of antidepressant, anxiolytic, antipsychotic, seizure-control, mood stabilizer, and stimulant medication occurs alongside medication targeting gastrointestinal- or sleep-related difficulties (Goin-Kochel et al. 2009). Beyond the clinic, parents may administer complementary and alternative medicines (CAMs) to their children or subject their children to dietary regimens such as wheat-free and/or dairy-free diets or high doses of vitamins. Of the psychological interventions, speech language therapy, occupational therapy, iABA therapy, and orthodox behavioral therapies are the most

commonly funded and therefore most engaged internationally. Of note, while many of the psychological interventions differ substantially in their target symptoms and behaviors, they still apply the treatment modality characteristics of behavioral therapy such as operant, classical, and vicarious conditioning.

Though some advocate strongly for a parental voice when choosing interventions for their child, the time-critical nature of ASD-related interventions requires parents to make important decisions at a time when they may be in shock and highly emotionally charged following the delivery of their child's ASD diagnosis. While parents have a duty of care to their child, pressure to immediately begin interventions can be overwhelming, and parents may experience choice overload in the face of the sheer number of available interventions and conflicting information about their efficacy. In the face of inadequate information, and beset by negative emotions and feelings of worry for their child's future, parents will often subscribe to any intervention on offer while adopting a wait-and-see approach. Of concern, rather than choosing multiple interventions as a strategy to treat a complex disorder, the concurrent use of evidence-based and non-evidence-based interventions is more likely a representation of the sheer desperation and frustration felt by parents. Accordingly, research suggests that at any one time, parents are trying up to seven types of intervention with their child, which in turn may be placing immense strain on parents and the greater family unit. That some of these interventions are ineffective and financially punitive demonstrates that parents are not getting the support they need when making decisions about their child's interventions. To that end, in order to better support parents in their intervention decisions, it is important to catalogue the reasons why parents engage or avoid specific interventions.

Current Knowledge

Inspection of the research to date suggests that parental decisions regarding their child's ASD-related interventions can be grossly classified into

three outcomes. First, and for whatever reason, parents are in opposition to the intervention, and therefore the decision is made for their child not to engage it. Second, the parent wants their child to participate in the intervention and has the psychological and physical resources to ensure that their child receives that treatment. Third, there is a strong desire on the part of the parent for their child to receive a particular intervention, though for whatever reason there are barriers preventing the child's engagement. For the first and second outcomes, it is of interest to understand what is driving the parent's decision, especially in relation to child characteristics or external influences. For the second and third outcomes, the interest lies in those facilitating or impeding factors, both internal and external to the parents, that determine whether their child receives a specific intervention or not. In relation to the second outcome, it is also of interest to know why parents, having started their child in a particular intervention, make the decision to continue or discontinue it.

When a parent that has the means and circumstances to enrol their child into an intervention and expresses opposition to do so, then their decision is typically motivated by ideology, skepticism, concerns for child safety or acceptance, and, relatedly, professionalism or personability of intervention providers. In terms of ideology, cultural, family, and religious factors may influence how parents attribute causality to their child's condition and consequently their choice of intervention. Interventions that do not conform to a family's belief or culture may be sternly opposed, and data from the USA suggests that one in five Americans are exposing their children to faith-based therapies (Miller et al. 2012). The notion that parental skepticism may be driving the nonengagement of some interventions indicates that some parents may in fact be referencing scientific evidence and not conforming to the "initiate-wait-then-evaluate" pattern floated in the literature. Remarkably, however, skepticism may not be related to whether an intervention has received backing from the scientific community. In an Australasian study (Shepherd et al. 2018), it was reported that iABA therapy, which is considered the gold standard intervention to which others should be

benchmarked, attracted equivalent numbers of skeptical parents as dietary interventions which are arguably a polar opposite in terms of established efficacy. Further, proven effectiveness of an intervention may not carry much weighting if parents prioritize symptoms that are not targeted by that intervention and are perceived as less urgent, and the individual needs of the child commonly determine if an intervention is rejected. In terms of safety and intervention side effects, it appears that parents have reluctance to engage with biological treatments when their children are younger, where medicine is tried as a last resort. Generally, however, parents find it difficult to judge the safety of interventions, and whether an intervention is evidence-based or not may hold little sway over how parents perceive risk. Finally, parents may hear word of mouth that a particular service provider has been disrespectful to parents or children, leading them to outrightly reject the idea of their children being treated by that provider and thus taint that intervention modality.

Signing up children for ASD-related interventions typically brings substantial time and financial pressures to parents, and yet the evidence shows that children are on average exposed to 3–4 interventions at any one time. It is therefore of interest to understand the reasons why parents take on this "tyranny of interventions" and why they choose the interventions they do. In the ASD literature, it has been argued that the major influence of parental decision-making is endorsement from others, including medical professionals and therapists, friends and relatives, other parents of a child with ASD, and even celebrity promotion of "fad" interventions. Overall, it appears that parents place greater weighting on advice dispensed from professionals (e.g., medical doctors, therapists, and teachers) than from nonprofessionals. However, this may be a double-edged sword as when seeking advice from professionals, parents may be vulnerable to professional recommendations based on "professional opinion" rather than guided by evidence-based practice. This is of concern as it is often those professionals involved at the time of diagnosis that have a major influence on a child's intervention trajectory. Rightly or wrongly, however, parents generally view

medical professionals as trusted authority figures, and as such professionals need to base their recommendations on empirically supported interventions and not on personal beliefs. A further influence, though one has yet to be studied in sufficient detail, is the influence of the Internet and social media upon parental intervention decisions. Though findings to date have been mixed, the fact that parents rely heavily upon social media as a source of social support would suggest that other parents with ASD children maybe exerting a greater dominance than hitherto detected in past studies (Shepherd et al., 2020). An issue arises here in that taking advice from another parent with an ASD child may not lead to the best intervention outcome given the heterogeneity of symptom profiles across the autistic spectrum.

For many parents, the load of managing an ASD child, a family, and work life impedes the ability to access or interpret the body of scientific literature dedicated to intervention efficacy. Studies generally show that when selecting interventions for their children, parents are not especially motivated by whether the intervention is backed up by empirical evidence or not, as can be seen with the uptake rates of unvalidated dietary interventions. Instead, parents may be guided by “gut feelings” about services and the prioritizing of staff knowledge, experience, and skills over scientific evidence. This can be compared to what is known as the “dodo effect” in psychological practice, whereby the rapport (or “therapeutic alliance”) between a client and their therapist is argued to better predict the treatment outcome than the type of therapy itself. Intuitively, however, it is understandable why parents may be drawn to intervention services with staff possessing strong interpersonal skills and clinical experience, and because many services begin with an initial assessment of the child, parents are provided with an opportunity to form opinions of the staff and decide whether or not to engage with this intervention provider. What is clear, however, is that emotional factors weigh heavily on the decisions that parents make, and the general consensus is that parents are more swayed by glitzy advertisements freighted anecdotal reports and

“word of mouth” than scientific evidence. What is more, this shunning of the scientific evidence is not dependent upon the level of education, where even those with university-level qualifications may be vulnerable to “gut feelings” or parental intuitions that are driven by fear of missing out on the “next big thing” in ASD intervention or by worry of regression in their child’s progress to date. Consequently, parents may not disclose the use of interventions that lack empirical support to their doctors and therapists, suggesting that on some level they have a knowledge that their decisions may be cavalier or even dangerous to their child but at the same time not wanting to be criticized or pressured to disengage.

Fortunately, across the limited number of studies investigating parental choices of their child’s ASD-related interventions, it is clear that most decisions are child-centric and that the individual needs of the child are the overriding factor. Specifically, symptom type and symptom severity appear to carry the greatest weight when parents are mulling their child’s interventions; for example, speech language therapy would be selected to target communication difficulties. These findings indicate that either parents are considering the functional abilities of their child and prioritizing accordingly or else the services on offer are doing an effective job of matching interventions to typical ASD symptoms and severity thereof. However, not only does parental rating of their child’s ASD symptom severity guide intervention choice, but proportionality also determines the number of interventions engaged. In the USA, differences in parental intervention choice have been shown to vary as a function of child diagnosis, both for the types and numbers of interventions chosen. Pertinently, and with reference to DSM-3 diagnostic criteria, those with autism or PDD-NOS (pervasive developmental disorder-not otherwise specified) typically engage in more interventions than those with Asperger’s syndrome, and they are generally more psychological in nature. Beyond the core symptoms of ASD, parents also have to grapple with comorbid problem behaviors and deficits in everyday skills that impede child function. In terms of the latter, parents may be highly motivated to engage interventions that

address deficits in areas such as road sense, friendship, joint attention, and safety with strangers. Thus for parents, the presence of comorbidities and the lack of age-appropriate skills serve to further complicate intervention decisions.

Few studies exist that probe the reasons why parents choose to terminate interventions once they are in progress, though it has been suggested that, beyond the expected discontinuation that occurs when therapy goals are realized, such terminations are commonplace. On occasion discontinuation occurs when the child reaches an age, whereby that intervention is no longer funded, even though parents are satisfied with the outcomes of the intervention itself. Related cost is a common reason given by parents to terminate an intervention, and in countries where iABA therapy is not funded, parents on average incomes or less would struggle to meet payments. Research has shown that if parents begin to doubt an intervention's impact, they will likely cease engagement and potentially move to an untried intervention. This is especially evident as the child moves towards adolescence, where there is a noted shift from psychological to biological interventions. As the child gets older, the use of prescribed medicines increases, possibly driven by the emergence of problem behaviors during puberty that are otherwise not being treated by psychological interventions. That being the case, the discontinuation rate of medications is also reported to be high, possibly due to drugs that from the outset were designed to target other conditions and were either not benefitting the child or were causing unpleasant side effects. Predictably, parents will abandon interventions if they perceive their child to be in pain or discomfort. Similarly, dietary interventions are commonly ended by parents due to a perceived lack of progress, constituting wasted time and financial resources that would have been better spent on validated interventions. However, even though parents may be dissatisfied with an intervention, they may still persevere if it provides them with respite.

Related to those parents who are able to engage their child in a specific ASD intervention are those parents who desire to engage but encounter barriers. On this point it is important to acknowledge that the nonengagement of an intervention does not

always signal parental opposition *per se*. Firstly, some interventions are simply not available to be selected by parents due to factors such as geographical location. Where an intervention is not offered in the immediate locality of the family, the only choices are to miss out or uproot the family and move to a place where the intervention is offered. For other parents, the intervention may be within their commuting range, but they are just unaware of the service's existence. In this scenario, it may be that practitioners are failing to fully inform parents about the broad spectrum of available interventions in their area. It has been suggested that in clinical practice, therapists are reluctant to inform parents about evidence-based interventions out of concern that the parents cannot afford it. Indeed, for some parents it may be that the intervention is accessible, but they do not have the financial resources for their child to engage it. Typically, expense is a primary reason why a parent might want to engage their child in a particular intervention but does not, and consequently government-funded interventions are much more likely to be chosen than those interventions that are self-funded. There is no evidence that parents who do not oppose a specific intervention and can afford to enrol their child still refuse to engage on the basis of cost. Instead, there is evidence that parents borrow or obtain funding by other means to get their child the support they need, including bank loans and, in the case of stem cell implants, "crowdfunding" over the internet.

The inability to effectively manage time given the demands of caring for a child with ASD might also be expected to make parents avoid particular interventions, but there is currently mixed evidence as to whether time constraints are a barrier to their child engaging an intervention, nor are time-related barriers commonly cited as a reason to discontinue an already-engaged intervention. On the face of it, this comes as a surprise, given the extensive parental involvement demanded by many of the mainstream psychological interventions, and as such may reflect parent's commitment to their child. Indeed, one study discusses the importance of intervention "fit" in relation to families' schedule and routines (Goin-Kochel et al. 2007) and the pressure placed on parents to oversee home-based

interventions. Despite the daunting task of collaborating in their child's interventions, most parents seem to "just get on with it" and engage in interventions irrespective of the resulting stress or the strength of their support networks to sustain them. Finally, child characteristics such as age and extreme problem behaviors may also prevent parents from choosing some types of interventions. For psychological interventions age is an important consideration as the child needs to be mature enough for a structured approach, while for biological approaches the use of elimination diets seems more popular in early childhood, perhaps as parents have greater control of their child's diet. Further, it appears that practitioners are less likely to advocate medication until children enter adolescence.

Future Directions

While cases of ASD are increasing globally as an expected consequence of population growth, there is convincing evidence suggesting that the prevalence rates of ASD are also increasing. Consequently, the economic burden of ASD is likely to increase, and not only does this increase demand for effective interventions, but it also entails parents to exhibit prudence when strategizing their child's intervention trajectories as demand and cost of interventions increase. In the defense of parents and their choices, the first step towards intervention optimization lies in the development and evaluation of a broader range of ASD-related interventions, and it would be unfair at the current time to judge parents on their choices when the selection of empirically assessed interventions is so thin. The next step entails formal support sources to be equipped with the knowledge to guide parents in their intervention decisions. Currently it is not clear whether parents are prioritizing other factors (e.g., "word of mouth") over research evidence because they are unaware of the importance or existence of research or if they are dismissing its importance in favor of other factors, including emotion-based factors such as "gut feelings." Though reluctant to engage in interventions that may be ineffective,

expensive, time-consuming, or even harmful to their child, parents may find themselves being unduly influenced by therapists or other parents with ASD children or else relying on gut feelings when they don't have the time or know-how to access research evidence. Future researchers may investigate whether the provision of information about evidence-based practice would influence the weighting that parents place on research evidence in their decision-making. On this matter, when considering external influences, more investigation needs to occur around the weighting that parents place on the informational sources themselves, that is, is the medium the message?

Research shows that when parents and practitioners collaborate in decision-making processes, the parents feel more invested and included in their child's health care (Herbert 2014). However, to facilitate joint decision-making processes, professionals need to be mindful that what they believe works best for the child may not be what works best for the parents or the greater family. With this in mind, and acknowledging that parents are the ultimate authorities of their child's treatment, professionals need to formulate treatment paths that optimize intervention outcomes while also being compatible with the larger family system. To this end it might be useful to produce a set of clinical protocols that can be adopted universally and continuously improved and adapted over time. However, challenges in producing a formalized set of practice guidelines exist in as much as substantial variations exist internationally and even within nations. Consequently, what will be effective in one locality may not be in another.

A further issue involves considering legislative frameworks and whether or not intervention choices should in fact be sitting entirely with the parent. Pertinently, the freedom of choice bestowed upon parents may create cases where children receive no intervention at all, which can arguably be considered the equivalent of withholding treatment. Ethically, the withholding of treatment is justifiable only when to do so is in the best interests of the child, and the "best interests" argument often underlies legal criteria which focus on the child's future quality of life, the effectiveness of treatments, and the broader costs versus benefits of

treatments. In the ASD context, it is not uncommon for parents to experience denial immediately following the diagnosis of their child or the emergence of their child's core symptoms. As such, they may refuse to enrol their children in interventions during time-critical windows of development. In such cases should medical professionals be seeking compulsory treatment orders for the child? Further, by not engaging their child in interventions, might parents be committing the equivalent of medical malpractice, and does this non-engagement constitute a form of negligence to which they should be held accountable? Alternatively, what if a parent insists on unproven interventions that are harming their child? Either way, the amount of responsibility put upon parents is one that evidently requires further discussion at the legal, medical, and societal levels.

Understanding Social Communication Differences in ASD and First-Degree Relatives

Definition

Social communication deficits are a defining feature of autism spectrum disorder (ASD). Evidence suggests that first-degree relatives of individuals with ASD also demonstrate differences in social communication that mirror those observed in ASD in quality but are subclinical in expression and not associated with impairment. Differences in attention and social processing may underlie the social communication impairments in ASD and more subtle differences observed in relatives. Understanding the roots of social communication phenotypes among clinically unaffected first-degree relatives of individuals with ASD may be a particularly powerful way to understand the

cognitive, neurobiological, and genetic contributors to core symptoms observed in ASD. This entry focuses on allocation of visual attention as a possible contributing mechanism to social communication profiles in individuals with ASD and their parents.

Historical Background

When first formally describing autism in 1943, child psychiatrist Leo Kanner observed that the parents of individuals with autism spectrum disorder (ASD) often exhibited subtle personality traits, such as social reticence, that mirrored in quality certain features of autism. Unfortunately, at that time this observation was misinterpreted as evidence that a detached parenting style was a causal factor in autism. It would be several decades before the genetic heritability of ASD was firmly established by the landmark twin study of Folstein and Rutter (1977), who also demonstrated among co-twins who did not have ASD features that resembled those observed in ASD in quality but that were not as severe in expression. Substantial evidence now exists documenting the strong genetic basis of ASD, and a number of high confidence risk loci have been identified (Chaste et al. 2017; Tick et al. 2016). In spite of strong genetic effects, however, the causes of ASD are heterogeneous, with most cases due to polygenic genetic effects, and less than 1% explained by any specific molecular genetic variant. Studying subclinical traits observed in family members of ASD is one means of reducing etiologic heterogeneity, by identifying heritable traits that can be used to stratify families into more homogenous subgroups. Further, the study of such traits in relatives may also help inform etiologic mechanisms of ASD by helping to decompose the complex ASD phenotype into more fundamental component features with clearer ties to underlying biology and in the absence of clinical comorbidities commonly observed in ASD (Losh et al. 2008; Lowe et al. 2015).

The constellation of subclinical traits observed in relatives has been referred to as the Broad

Autism Phenotype, or BAP. Such traits appear to be more strongly expressed among parents from multiplex families than simplex families, suggesting that they are sensitive indices of genetic liability to ASD (Bernier et al. 2012; Losh et al. 2008; Virkud et al. 2009). Given the ubiquity of social communication deficits in ASD, an ongoing area of research has been to characterize social communication features of the BAP, as well as potential cognitive underpinnings of social communication differences, in individuals with ASD and first-degree relatives. This entry focuses specifically on this line of research and in particular an investigation into concurrent narration and visual attention in individuals with ASD and parents.

Current Knowledge

Social Communication in Autism Spectrum Disorder (ASD)

Social communication differences are universally observed in ASD. Difficulties include difficulties with reciprocity (i.e., building on a conversational partner's statement), overly formal language, off topic remarks, introduction of topics without providing adequate background information, and difficulties with suprasegmental features of speech such as reduced variation of intonation (de Villiers et al. 2007; Diehl and Paul 2012, 2013; Diehl et al. 2009; Lam and Yeung 2012; Klusek et al. 2014). Prior work suggests that individuals with ASD also demonstrate difficulties with narration (i.e., storytelling), with particular difficulty imbuing narratives with a psychological perspective to explain protagonists' actions and motivations (Colle et al. 2008; Lee et al. 2017, 2019; Losh and Capps 2003; Losh and Gordon 2014; Loveland et al. 1990; Loveland and Tunali 1993; Tager-Flusberg and Sullivan 1995). Further, individuals with ASD appear to exhibit the greatest difficulty in communicative contexts that are less-structured, emotionally evocative, and open-ended, with relative strengths in highly structured contexts such as wordless picture books (Losh and Capps 2003; Lee et al. 2019).

Social Communication in First-Degree Relatives of Individuals with ASD

Relatives of individuals with ASD may also demonstrate social-communicative differences. Prior work has demonstrated differences in conversational contexts in parents with ASD that are more subtly expressed but qualitatively similar to those observed in ASD. Differences observed include overly lengthy conversational turns, topic preoccupation, tangential responses, and greater rates of total pragmatic (i.e., social) language violations in semi-naturalistic conversations (Di Michele et al. 2007; Hurley et al. 2007; Landa et al. 1992; Losh et al. 2008, 2012; Ruser et al. 2007). Differences in narrative skill have also been observed in parents (Landa et al. 1991). Landa and colleagues presented parents of individuals with ASD and adults without children with ASD open-ended story prompts. They found that a subgroup of parents of individuals with ASD produced narratives lower in complexity and coherence than those of controls (Landa et al. 1991). This finding is consistent with a number of studies showing that differences are evident only in a subgroup who demonstrate the personality and social-communicative features of the BAP. For instance, parents with the BAP have been shown to exhibit subtle differences in social cognition, including differences in reading emotional states from faces, biological motion, and complex emotional scenes (Adolphs et al. 2008; Losh and Piven 2007; Losh et al. 2009). BAP-specific differences have also been observed in studies of language processing in ASD and first-degree relatives, where parents with the BAP showed reduced language automaticity and differences in eye-voice coordination (a measure of efficient language processing) during rapid automatized naming tasks (Losh et al. 2010; Nayar et al. 2018). Together, these findings suggest that specific language and social phenotypes could reflect genetic liability to ASD and be useful in identifying subgroups of families who may be more similar in underlying etiologic factors.

Origins of Social Communication Differences in ASD and First-Degree Relatives

A critical next step in understanding the social communication differences in ASD and first-

degree relatives is to examine the mechanistic origins of such differences. Evidence suggests that impairments in social cognition are strongly related to the social communication difficulties in ASD, where problems reading emotions and psychological states can seriously limit conversation and narrative skills (e.g., Capps et al. 1998; Losh and Capps 2003; Ochs and Capps 2001; Tager-Flusberg and Sullivan 1995). Differences among first-degree relatives have also been observed in neuropsychological domains that are conceptually related to, and have been hypothesized to underlie, social communication difficulties in ASD. For example, as noted previously, parents of individuals with ASD may also show subtle differences in social cognition, such as reduced ability to identify emotions from eyes or interpret biological motion (Baron-Cohen and Hammer 1997; Losh et al. 2009; Losh and Piven 2007) and also exhibit differences in brain activation during such tasks (Baron-Cohen et al. 2006). Studies have also shown that differences in social cognition are correlated with social communication skills in parents of individuals with ASD (Losh and Piven 2007; Losh et al. 2009), suggesting that differences in social cognition may represent a genetically meaningful feature contributing to the core symptomatology of ASD.

Analysis of eye gaze may reveal mechanistic factors underlying social cognitive and subsequent social communication differences in ASD and among first-degree relatives. A substantial body of research suggests differences in allocation of visual attention in ASD. For instance, individuals with ASD demonstrate difficulty following the gaze of individuals in joint attention paradigms (Leekam et al. 2000) and show reduced fixations to social stimuli, particularly for scenes with multiple individuals (Klin et al. 2002; Rice et al. 2012; Sasson et al. 2008; see Chita-Tegmark 2016, for review), and reduced fixation to the eye region of faces and atypical visual scanning of faces (e.g., Corden et al. 2008, Dalton et al. 2005, Hernandez et al. 2009, Pelphrey et al. 2002, and Rutherford and Towns 2009), particularly when conversing about emotional topics (Hutchins and Brien 2016). Such attentional differences might seriously undercut social-communicative competence, making it difficult,

for instance, to read and track an interlocutor's interests and involvement in unfolding exchange, or focus on topics that are socially and psychologically salient to communication partners. Attentional differences during dynamic social scenes have indeed been found to predict greater language and social-communicative impairment in individuals with ASD (Jones et al. 2008; Klin et al. 2002; Righi et al. 2018; Speer et al. 2007). First-degree relatives of individuals with ASD may also show differences in visual attention, such as reduced attention to socially relevant aspects of videos (Groen et al. 2012), and differences in approaches to processing facial expression in those parents who show features of the BAP (Adolphs et al. 2008). These parallel differences suggest that visual attention may be an important mechanism contributing to the social-communicative phenotype in ASD.

In an attempt to further characterize social-communicative phenotypes and potential contributions of visual attention differences in individuals with ASD and first-degree relatives, Lee et al. (2019) examined narrative quality and patterns of visual attention during narration across two different contexts in individuals with ASD and their parents. The first was a more structured task during which individuals were asked to narrate a wordless picture book one page at a time. In this way, visual attention was captured simultaneously with narration. During the second task, both groups were presented with emotionally evocative, ambiguous images from the Thematic Apperception Test for 8 seconds and then asked to generate a narrative. This methodology allowed for comparison of narrative skills in individuals with ASD and first-degree relatives in the same social-communicative contexts, to further explore the role of context in observed differences and to explore how differences in visual attention might relate to differences in social communication.

Results indicated that individuals with ASD and parents of individuals with ASD demonstrated parallel patterns of performance, in that both groups showed differences in narrative quality from controls during the more open-ended task only. Further, subtle differences in visual attention were observed in both individuals with ASD and parents, with more pronounced differences

observed for those parents with the BAP. Findings indicated context-specific patterns of visual attention differences that were not always in line with those observed in prior work (although no prior studies have examined visual attention during narration). For example, both individuals with ASD and parents with the BAP allocated a greater proportion of visual attention to elements of the setting of a visually complex scene with many background details. However, individuals with ASD and parents with the BAP attended more to faces when telling stories about scenes where facial expressions figured prominently and the emotional content was more ambiguous. It may be the case that because groups were explicitly directed to narrate (including a direct prompt to say what characters were thinking and feeling), increased attention to social stimuli in these ambiguous contexts was needed to interpret characters' emotional states.

Interestingly, relationships between patterns of visual attention and narrative quality were not detected for areas in which individuals with ASD and parents of individuals with ASD differed from controls. For example, in response to the image in which individuals with ASD fixated more intensively on the setting than controls, it was an increased attention to characters' bodies that was related to poorer quality narratives. In other words, results suggested the possibility that individuals with ASD and first-degree relatives not only differ in allocation of visual attention but may also differ in how they make use of visual information to inform the content and quality of their narratives.

Although more work is needed to clarify the direct relationships between visual attention and social communication, findings from this study support earlier work showing that including relatives in studies investigating mechanisms underlying core features of ASD (such as social-communication differences), particularly as revealed through eye tracking, may be a fruitful avenue to identify neurocognitive contributors to social communication in ASD that may also index genetic liability. Findings documenting differences in visual attention also relate to prior findings in first-degree relatives suggesting more fundamental differences in the efficiency of eye

movements that map more directly to specific brain structures, such as the cerebellum. For example, Mosconi et al. (2010) found that first-degree relatives of individuals with ASD demonstrated ocular-motor differences such as minor inaccuracies in direction of eye movement and subtly reduced inhibition of eye movements. Differences in eye-voice coordination have also been observed in ASD and among parents in nonsocial, rapid automatized naming tasks requiring fluid scanning and naming of colors, objects, letters, and numbers (Nayar et al. 2018). Of note, similar differences in eye-voice coordination have been noted in carriers of the *FMR1* premutation (Nayar et al. 2019). Full mutations of the *FMR1* gene cause fragile X syndrome, the most common inherited cause of intellectual disability and also the monogenic disorder most frequently associated with ASD (e.g., Zafeiriou et al. 2013). Findings showing overlap between carriers of the *FMR1* premutation, who do not present with confounding intellectual disabilities associated with FXS, and parents of individuals with ASD, suggest a possible link between a gene known to confer risk to ASD and ocular-motor differences observed in ASD and in relatives. Together, such findings highlight how eye tracking may be applied to identify mechanistic differences, which may map more closely to underlying genetic and neurobiological variation, and potentially lead to downstream differences in the efficiency of allocation of visual attention in social settings and subsequent highly complex social-communicative phenotypes. Overall, identifying overlapping phenotypic patterns in ASD and among parents, integrating assessments of both social communication and allocation of visual attention, may clarify phenotypes that could be used in future studies of key features indexing genetic liability and the basis of the complex social-communicative impairments observed in ASD.

Future Directions

Future research should continue to employ a range of assessment methodologies to characterize social communication in ASD and incorporate

assessments in parents and other biological relatives to help clarify the complex ways in which genetic liability to ASD might express in clinically unaffected family members. Given work suggesting the impact of context on differences observed in both individuals with ASD and first-degree relatives, with greater differences observed in less-structured contexts, the development of more naturalistic assessments will be particularly important in elucidating features of social communication shared across groups. Further, incorporation of multiple methodologies, with additional research on concurrent eye tracking with language production, may shed light on neurocognitive underpinnings of these differences. It will also be important to compare first-degree relatives of individuals with ASD to first-degree relatives of other genetically based disorders impacting language (e.g., specific language impairment; Ruser et al. 2007), where social communication differences have also been observed. Such comparisons may clarify the specificity of findings to ASD as opposed to language-related disorders more generally.

Taken together, characterizing social communication in relationship to eye movement in individuals with ASD and first-degree relatives can help to guide investigations of gene-brain-behavior relationships in ASD. A robust body of work suggests that subtle differences in social communication occur at a greater rate in first-degree relatives of individuals with ASD (and particularly subgroups demonstrating broader features of the BAP) that mirror deficits observed in ASD and that these groups also show parallel differences in underlying neurocognitive factors proposed to contribute to social-communicative differences in ASD. Future research should continue to employ multiple methodologies, such as assessment of visual attention and other proposed neurocognitive contributors to social communication, to characterize this key phenotype in first-degree relatives.

Uniform Transfers to Minors

Definition

The Uniform Transfers to Minors Act, the successor to the Uniform Gifts to Minors Act, is a uniform law that has been adopted in 48 of 50 states, with two states enacting substantially similar statutes. The Uniform Transfers to Minors Act allows for parents and other donors to transfer property or assets to minors. Because a minor does not have the legal capacity to manage property, the property can be transferred to a trust for the benefit of a minor. This accomplishes the donor's goal of having the property benefit the minor, but this setup still has oversight by a trustee who does have the legal capacity to manage the property and use it for the benefit of the minor. When the minor reaches age 21, the property in the trust is distributed to the minor.

One benefit of this kind of a transfer of property is that the donor, usually a parent or grandparent, can appoint the custodian of the property. The custodian is the person appointed to hold the property for the benefit of the minor. To create a custodianship, the donor can simply fill out a form available at a bank or other financial institution. By doing this, the donor can ensure that he or she is deciding who is keeping the property for the benefit of the minor. Under Section 14(a) of the Uniform Transfers to Minors Act, a custodian can use the property for the benefit of the minor without a court order when the custodian deems it advisable. Under Section 12 of the Uniform Transfers to Minors Act, the custodian can invest and manage the property as long as they are doing so in accordance with the “prudent person” standard.

The other main benefit to using a trust under the Uniform Transfers to Minors Act is the significant tax benefit. If property is given to a minor in this form, the gift of property will qualify as a present interest and therefore be eligible for the federal annual gift tax exclusion. In 2010, the

Unengaged

► Passive Group

annual exclusion allowed for a person to give away \$13,000 to another person without paying any gift tax as long as it was a gift of a present interest. According to the Internal Revenue Service (“IRS”), a present interest is the “unrestricted right to the immediate use, possession, or enjoyment of property or the income from such property” (Treas. Reg. § 25.2503(b)). Under the Internal Revenue Code, for a gift to be a gift of a present interest to a minor and eligible for the annual gift tax exclusion, it must meet three requirements that can be written into the terms of a trust under the Uniform Transfers to Minors Act. These provisions allow property to be used for the minor before age 6. If the property is not used before age 21, the statute mandates that it be distributed to the minor at age 21. If the minor dies before reaching age 21, the property passes through the minor’s estate or as appointed by the minor. Finally, the statute prohibits any substantial restriction on the trustee’s discretion to use the income from the trust (I.R.C. § 2503(c) and Treas. Reg. § 25.2503-4(b)).

The Uniform Transfers to Minors Acts enables a family to make gifts to a minor in a structured and cost-effective manner. Not only will the family be able to ensure that the minor will be taken supported, but they will also be able to take advantage of significant tax benefits by using this structure.

Upright/Inverted Figures

Definition

The use of upright/inverted figures is a research paradigm in which an image typically expected to be in one orientation (i.e., the “upright” orientation) is shown upside down (i.e., the “inverted” orientation) in order to disrupt typical visual expectations. The discrepancy between performance on a marker task, such as recognition (e.g., “who is shown in this picture?”), in upright

and inverted conditions is known as the inversion effect. Since the low-level perceptual differences between an upright and corresponding inverted image are minimal (e.g., both would be equally bright, contain the exact same contrast profiles, the same colors, etc.), the inversion effect is assumed to be associated with removing the upright image from its original context, that is, shattering configural processing or holistic orientation (Rakover and Cahlon 2001). One class of commonly used upright/inverted figures is human faces. When faces are shown upright, they are easily recognized and classified. However, when faces are shown upside down, identification becomes more labored and processing more difficult. This phenomenon is the face inversion effect, and often seen in older typically developing children and adults (Gauthier et al. 2010). Children and adults with autism have been shown to exhibit the face inversion effect to a lesser degree than controls, and the results of many studies have suggested that individuals with autism process faces in a featural or piecemeal manner (i.e., focused on specific individual features) rather than in the configural or holistic manner employed by typical peers (Bowler 2007). Faces are not the only class of stimuli that exhibit atypical inversion effects in individuals with autism. For example, the preference for stimuli such as point-light displays of people walking shown side by side, one upright, and one inverted, is heavily skewed toward upright walking in typically developing individuals but not in individuals with autism (Kaiser and Shiffrar 2009).

Background and History

The diagnostic concept of autism was introduced in Uruguay by Professor Luis E. Prego Silva in 1951, after returning from an internship as a child and adolescent psychiatrist at the Harriet Lane Clinic of the John Hopkins Medical School in Baltimore, Maryland. At that time, Professor Prego created a multidisciplinary team aiming at conducting research and treatment for children with autism, in the Department of Child Psychiatry of the Pedro Visca Hospital (Main Pediatric hospital of the time) (Cherro and Trenchi 1997).

However, the influence of psychoanalytic thought in the River Plate area determined an important delay in the expansion of the understanding of autism as a neurodevelopmental disorder. While treatment modalities advanced in other regions of the world, in Uruguay, they were heavily influenced by the psychoanalytic theory. During many decades, intervention was

centered in unstructured programs based on psychoanalytic psychotherapy.

During the 1990s, with the stimulus of Professor Miguel Cherro Aguerre, the incorporation of DSM III-R, and then, DSM IV to the educational programs of Child and Adolescent Psychiatrists first, and then, to other pediatric specialties, allowed the progressive unification of diagnostic criteria. It was at that time that the first parental advocacy group began. The publication of the book *Autism, Revising Concepts* by Professor Prego Silva (1999) gave place to the integration of different theoretical approaches and therapeutic practices.

In 1987 the first public educational center for autism and infantile psychosis was created. This institution was meant to provide education to those children with severe autism. During a decade, students of Child and Adolescent Psychiatry carried out compulsory internships in the above-mentioned center, where they participated in a multidisciplinary team. Regretfully, there was no further advance and no other public centers were created.

In 2003, a meeting that highlighted the difficulties and needs from the diagnostic, therapeutic, preventive, and juridical stand-point was carried out, with the support of the PAHO, the National Minor Institute and an international table for Childhood with special needs (MINCAD 2003). In the national psychiatry field, consensus was reached to incorporate DSM IV and CIE 10 and abandon the use of other nosographies (Garrido and Viola 2006).

In the year 2005, responding to the increase in the need of improving early detection, diagnosis, and treatment of children with Autism Spectrum Disorders (ASD), a specialized outpatient clinic for diagnosis and treatment of children and adolescents with ASD was created at the Centro Hospitalario Pereira Rossell (main public pediatric hospital). As part of the National Childhood Health Program developed by the Ministry of Health, early signs for ASD and other developmental disorders were incorporated to the child's health record (tool of universal and compulsory use within Uruguay) (Programa Nacional de Salud de la Niñez-MSP 2007). Afterwards, in the framework of the Integrated National Health

System (SNIS, from its initials in Spanish), systematic developmental surveillance was established, in the first level of attention and a National Guideline for developmental surveillance for children aged 0–5 was elaborated (Programa Nacional de Salud de la Niñez-MSP 2010). These instruments, together with a greater awareness about Autism in society as a whole, contributed to earlier diagnosis.

Parent advocacy groups grew and expanded, with the creation of some treatment centers in the capital city (i.e., Montevideo) as well as in some of the provinces. In the year 2010, the Uruguayan Autism Federation (FAU, from its initials in Spanish) was created. The Federation, which gathers most of parental associations of persons with ASD, obtained participation in state organisms which implement and control social policies that address disability (National disability commission, group for the educational improvement of persons with autism from the National Administration of Public Education, etc.).

Legal Issues, Mandates for Service

In 1989, there was an unsuccessful attempt to enact the protection of people with disabilities (Poder Legislativo ROU 1989). It was only many years later, in 2010, that a law concerning rights of persons with disabilities was enacted: Law 18.651 for the Integral Protection of persons with Disabilities (Poder Legislativo ROU 2010). The aforementioned law considered the ratification of Uruguay of the Convention on the rights of the Child (UN 1989) and the Convention on the Rights of Persons with Disabilities (UN 2006).

A direct benefit that resulted from Law 18.651 is that many children, adolescents, and adults diagnosed with ASD with severe disability were contemplated within the Personal Assistants Program, in which personal assistants are financed by the Uruguayan state. Articles 35° to 37° of this law established the state's responsibility in the implementation of strategies to support and contribute to early detection of the disability, in providing timely attention, and the mandatory declaration of persons with disabling conditions, regardless of their age. The greatest contribution

has been the Protocol for Educational Inclusion of Persons with Disabilities in educational centers (Decreto N° 72/017), since in Uruguay there was a considerable delay concerning guarantees for inclusive education for children and adolescents with ASD and other disabilities.

Yet, apart from this legislation for the protection of rights of people with disabilities in general, there is still no other legal recognition of Autism in Uruguay. In 2014, as an initiative of parent advocacy groups and some legislators, a bill to create an Integral System of Prevention and Treatment for ASD was presented to the Public Health and Social Assistance Commission. This bill has not yet been considered in Parliament.

Overview of Current Treatments and Centers

Since 2007, the Health System in Uruguay is organized as an integrated system (SNIS) that joins public and private health providers through a National Health fund (Poder Legislativo ROU 2007). The SNIS widened general health coverage of the population, particularly for children and adolescents. Every person with ASD has access to a pediatrician, and to specialists in pediatric neurology and child and adolescent psychiatry. However, the access to treatment and rehabilitation continues to be considerably uneven and partial.

According to an extensive survey for parents of persons with ASD, conducted in six Latin American countries in 2016 (Garrido and García 2017), in Uruguay 64% of patients had received language therapy at some point and 73% psychomotor treatment. These treatments are covered by the state for a maximum of 3 years. Despite strong international evidence, other treatments such as behavioral therapy, cognitive therapy, and occupational therapy are not financed by the Health System.

In Uruguay there is an important network of multidisciplinary centers, which are distributed across the country. They all provide attention from professionals of different areas (language skills, psychomotor skills, psychology, and pedagogy). There are centers which provide comprehensive specific attention for patients with ASD,

organized and managed by parental associations, with partial support from the state and others run by groups of independent professionals. These centers are still scarce and access to them is not universal nor equitable.

Regarding the educational system, there are two public schools specialized in ASD, one in the capital city and another in the province (Salto City), with a very limited capacity. There is a greater number of schools (82) specialized in intellectual disability and distributed throughout the country. Support teachers that come from special schools and cooperate with the inclusion of children with special educational needs are available. However, the number of support teachers remains limited, and there is a considerable gap between the need and offer of this service, added to a heterogeneous distribution throughout the country.

One third of children and adolescents with ASD attend special education centers for intellectual disability, and only 26% of those who attend regular schools receive some kind of additional support in the classroom, according to a survey conducted with caretakers in 2016 (Garrido and García 2017).

Despite of the fact that Uruguay has a greater number of qualified human resources in different disciplines than other countries in the region, it is still essential to continue to go forward in specific qualification and improve accessibility to more intensive evidence-based treatments.

Overview of Research Directions

Research in the autism field is scarce in Uruguay. This is partially due to the obstacles in obtaining financial support and to the fact that clinicians distribute their time between assistance to patients, teaching, and research. Research projects, centered in the University of the Republic (Udelar, for its acronym in Spanish) and in one private university (Uruguayan Catholic University), are in some cases financially supported by the National Agency for Investigation and Innovation (ANII, for its initials in Spanish).

There are no epidemiological studies for ASD in Uruguay. The first estimation of prevalence is

0.9% for Uruguayan children under the age of 4, and was drawn from the data of the First National Survey of Nutrition Child Development and Health (ENDIS) (Cabella and Vigoritto 2016). This survey included the administration of the Child Behavior Checklist (CBCL 1 ½–5 for parents) to determine emotional and behavioral problems in preschoolers. It relied on the use of the withdrawal scale and pervasive developmental disorders scale of the instrument. Specificity and sensibility of both scales had been established previously for Uruguayan preschoolers (Garrido 2015).

The Latin American Autism Network (REAL from Spanish initials) has been created recently. REAL gathers various countries in the region and has enabled cooperative work. In 2016, six of its members (Argentina, Brazil, Chile, Uruguay, Dominican Republic, and Venezuela), with the support of Autism Speaks, carried out a family survey, about the needs, impact, and stigma perceived by caretakers of persons with ASD (Rattazzi 2016). Regarding Uruguay, information concerning diagnosis, treatments, schooling, impact in families, quality of life, and participation in parental groups was gathered from 382 families.

A new collaborative ongoing project, in the framework of REAL, is the adaptation and validation of the Parents Skills Training Program (PST), developed by the WHO and Autism Speaks. This will allow a greater accessibility to early intervention for children with ASD in many Latin American countries.

In the specialized outpatient clinic for ASD at Pereira Rossell Hospital, clinical research about conditions associated with ASD were carried out. These include Sleep Characteristics in Preschoolers with ASD (Tailanián 2015), Early Language and Social Skills Regression (Amigo 2014), and ADHD (Garrido and Ceretta 2013).

Overview of Training

Since 2003, a module concerning ASD has been included in the child psychiatry course for pediatric residents. The latter is compulsory and is

centered in early detection. The implementation of the surveillance guide for children aged 0–5 was accompanied by training on normal development and frequent developmental disorders, for pediatricians and family doctors throughout the country. ASD was specially considered.

In 2013, the Uruguayan Association of Child and Adolescent Psychiatrists carried out an ADOS workshop, where 30 child and adolescent psychiatrists (one third of all child and adolescent psychiatrists in Uruguay) were trained in the administration of the instrument as a complement for clinical diagnosis.

Clinical psychologists, speech language therapists, psychomotor skills therapists, occupational therapists, and educators receive training in different intervention models, but the public offer of specific training is still very limited.

In the framework of an agreement of the Faculty of Medicine (UDELAR), and the University of New México, USA, the project for Extension for Community Healthcare Outcomes (ECHO) has been implemented in Uruguay, under the coordination of Prof. Henry Cohen. The aim of project ECHO is to democratize knowledge and improve the attention to complex and prevalent health problems. Since 2015, the Department of Child and Adolescent Psychiatry of the Faculty of Medicine (Udelar) carries on teleclinic ECHO-ASD with the objective of training first level health professionals in the country from different health providers, in early detection and comprehensive treatment for patients with ASD (Santoro et al. 2015).

The University, through the specialized ASD outpatient clinic of the Pediatric Hospital, has cooperated with the educational sector training resources from early childhood, primary and secondary education by carrying out conferences, workshops, and courses nation-wide.

Social Policy and Current Controversies

In the last years, awareness in the general population, regarding ASD has increased. Among other causes, this is due to the growth of the parental movement and the constitution of the Uruguayan

Autism Federation. As noted earlier, the FAU has obtained participation within programs and organisms that define social policies related to disability. It is important to highlight the existing cooperation between parental associations and many professionals. In this cooperative framework, a variety of initiatives regarding ASD have been carried out, such as support groups, some of the above mentioned research projects, and attention centers. Yet, the access to diagnosis, medical attention, and specialized treatment is not universal nor equitable. It is important to consider that there is still an average gap of 34 months between first parental concerns and diagnosis (Montiel Nava 2017).

Social security in Uruguay contemplates a pension for persons with severe disabilities, the provision of special assistance (personal assistants), in the framework of the National Care System, to those highly dependent individuals, as well as the access to certain treatment modalities.

As mentioned previously, Uruguay has an important network of multidisciplinary centers that provide attention in different areas. Rehabilitation treatments, in the above mentioned centers, are financed by the state, through social security, and given to children with specific developmental disorders and other emotional or behavioral problems. However, even though interdisciplinary treatment is provided to children and adolescents, comprehensive specific treatment for ASD is not fully financed by the state. This kind of treatment is mainly financed by the families of children with ASD. The incorporation of evidence-based treatments to the SNIS is still required. Certain treatments that show little or no evidence but are still used by families continues to be controversial.

Social security In Uruguay also contemplates that persons with severe disabilities receive a pension from the state.

In spite of the earlier noted difficulties and challenges regarding ASD in our country, Uruguay is undergoing a favorable period, and it is in the path of improving early detection, treatment strategies, and social inclusion for persons with ASD. Greater awareness about ASD in the Uruguayan society is notorious, as well as a rising

interest of professionals to become more knowledgeable in the subject.

US Social Policy and Autism Spectrum Disorders

³Legislative Affairs, Association of University Centers on Disabilities, Silver Spring, MD, USA

Introduction

Any formal decision made by a publicly mandated organization which is intended to directly or indirectly improve practices addressing the welfare of a population of people with an autism spectrum

disorder or ASD and their legal guardians in the United States.

Inclusion/Exclusion Criteria

Though many individuals and organizations may act in ways to improve welfare of people with ASD, this definition of social policy focuses on a subset of actions and excludes others.

- *Formal decisions* shift the emphasis to practices specified in some written form, as opposed to unwritten, informal, hypothesized practices (e.g., historical trends, institutional culture, and so on). Examples of such formal decisions include laws (and their associated regulations), professional practice standards, and formal position statements as long as these directly address practice.
- The focus on *practices addressing a population* excludes decisions made on a case-by-case basis, and emphasizes practices intended to address a specific population defined a priori, perhaps including a reference to other characteristics (age, presence of intellectual disability, and so on).
- Emphasizing practices affecting *people with ASD* exclude those originally developed to benefit people with related disabilities (such as intellectual disabilities), even those practices that people with ASD might benefit from them.
- Decisions that *indirectly improve practices addressing the welfare* of people with ASD allow the discussion of policy to be extended beyond services and supports provided directly to people with ASD, to actions that may benefit those professionals providing the services, such as training and applied research (see below).
- Decisions made *by an organization* exclude the actions taken by individual professionals in the care of their patients, students, or clients.
- Decisions made by a *publicly mandated organization* focus on practices intended to be universally accessible and exclude policies set by nongovernmental agencies unless the agency has a formal or de facto mandate to establish policy governing a broad population of people

with ASD and the groups of professionals who work with them (for example, the American Academy of Pediatrics).

- Including *legal guardians* acknowledges the primary role played by parents and caregivers, and their own need for support.

A more detailed discussion of social policy pertaining to ASD is available elsewhere (Doehring 2013)

Historical Background

Throughout history, the welfare of people with ASD has been affected by a wide range of social policies as defined above. Though the focus here is on those policies specifically designed for the population of people with ASD, a number of policies for related populations enacted in the 1960s and 1970s in the United States are worthy of note.

Early Legislation

The Rehabilitation Act (1973) was the first act to address the notion of equal access of people with disabilities. The Developmental Disabilities Assistance and Bill of Rights Act (or DD) introduced the term “developmental disability” to describe a range of significant lifelong disabilities with an early onset that included autism and focused on broad systems change, professional development, and legal protections. The passage of the Education for All Handicapped Children Act in 1975, renamed the Individuals with Disabilities Education Act in 1990, was another watershed in the development of school-based services and supports for people with disabilities, including those with ASD. In the field of mental health, the trend towards deinstitutionalization forced the development of new community-based systems of supports for those persons whose psychiatric conditions or developmental disabilities appeared to prohibit living at home as children or living independently as adults. These policies and trends, together with others, were part of a growing awareness and acceptance of disabilities beginning in the 1960s which led

directly to an increased commitment to develop community-based supports. To this day, these policies and trends continue to impact services for a broader population that includes people with ASD.

The Role of Advocates

Most changes in social policy regarding ASD over the past 35 years can be traced to the work of advocacy organizations. These organizations initially sought to raise awareness and, over time, urge the development of specific programs of services, research, and training. The establishment of Autism Society of America in 1965 gave advocates a voice at the state and national level through a network of local chapters and fostered collaboration between caregivers and professionals in formulating policy recommendations based on the presumption that autism is a lifelong developmental disability. Other groups such as Cure Autism Now and National Alliance for Autism Research (later merged into Autism Speaks) sought to define policies and set priorities for autism research often based the characterization of autism as a disease that can be cured or ameliorated. The advocacy organizations initially sought to raise awareness of autism by identifying it as a distinct disability meriting specialized educational and mental health services. State advocacy groups led policy initiatives to create a first wave of autism-specific programs in states such as Delaware, West Virginia, and Indiana in the 1970s and 1980s. These programs provided a range of services at the state level, such as disseminating information, providing training, developing and delivering services, and conducting research (Doehring 2013).

The Role of Research

The contribution of ASD research in the evolution of social policy is more complex (Doehring 2014). Within the broader community, the growth of social policies specifically designed for people with ASD has generally paralleled our understanding of the disability and the refinements in the definition of autism in the DSM. Within the scientific community, awareness grew with research specifically targeting autism and with

the rise of autism-specific periodicals beginning with the establishment of the *Journal of Autism and Childhood Schizophrenia* in 1971. Despite continued advances in the scientific understanding of ASD throughout the 1970s, 1980s, and 1990s, the adoption of new categories and labels did not result in immediate or universal changes in associated social policy. For example, autism emerged as a distinct disability in 1980 in the DSM-III following advances in research, but new state and federal regulation defining autism for the purpose of providing educational services emerged slowly and inconsistently and in many cases still fails to capture all of the defining features of autism. A broad range of studies contributed to the decision to include Asperger Syndrome or AS in the DSM-IV in 1994, but few public policies specifically and explicitly include AS. Part of the lag can probably be attributed to the relative lack of research directly relevant to social policy and inconsistent collaboration between researchers, service providers, policymakers, and advocates (Doehring 2013; Doehring 2014).

In other cases, advocates were able to draw on research findings to press their case for changes in social policy. This is illustrated by a second wave of initiatives intended to increase services for people with ASD. For example, Lovaas' (1987) claims – that almost one-half of preschool children who received early and intensive behavioral intervention or EIBI “recovered” and were not significantly different from typical kindergarteners – were repeatedly cited in costly lawsuits brought by individual parents to education agencies. These lawsuits effectively changed policy in pockets across the country, leading to the creation of autism-specific programs that sometimes provided more intensive services similar to those described by Lovaas. These changes almost always occurred only, however, at the local level – for example, in specific school districts or in county early intervention programs. As a result, services to young children with autism varied widely from one region or town to another, with services less likely to change in areas where advocates lacked organization and resources to lobby for change. Nonetheless, these successes set the

stage for more ambitious reforms led by parent advocates described below.

Research on the prevalence of ASD begun at around the same time also contributed indirectly to the development of related social policy. The first series of research sites in what would become the Autism and Developmental Disorders Monitoring (ADDM) Network was initially funded in 2000 in response to preliminary reports suggesting dramatically increased rates of autism in Brick Township, New Jersey (Peacock et al. 2013). Initial findings suggested markedly higher rates of ASD than previously thought and led some advocates to attribute apparent increases in prevalence to the increased use of the mercury-based preservative Thimerisol in childhood vaccines. This led to a change in national policy, phasing Thimerisol out of almost all vaccines, even though the hypothesized links between vaccine policies and rates of autism were disproven. Continued reports of increased prevalence fuelled public speculation about an “autism epidemic” and subsequently drove many policy initiatives at the local, state, and national level to increase services, training, and research.

Current Knowledge

There are too many potentially pertinent social policies to describe here, and no systematic survey of ASD policies enacted at the local, state, and national level has been conducted (see Doehring 2013 and 2014 for discussion of related issues) in the United States, let alone in other countries. This entry therefore seeks to provide a summary of the more significant social policies undertaken at the state and national level in the last 15 years in the United States, focusing within each area (services, training, research, advocacy on comprehensive reform) on local and regional policies only when state and national policies are absent. Lists of state and national policies can be found on the websites of advocacy organizations such as Autism Society of America (www.autism-society.org) and Autism Speaks (www.autismspeaks.org) and other networks such as the Association of University Centers on Disabilities (www.aucd.org). The National

Conference of State Legislators also maintains a searchable database of all state laws addressing autism (<http://www.ncsl.org/research/health/autism-policy-issues-overview.aspx>).

ASD Information and Awareness

The social policies most commonly adopted are those designed to increase awareness of and disseminate information about ASD and to coordinate efforts to establish other policies. That such policies are most common should not be surprising; these are also the core strategies adopted by most advocacy groups and are critical to building consensus towards more substantial policy. For example, many states have initiated some form of policy intended to gather information about ASD, though such policies can vary in important ways: the initiative can be time-limited (e.g., an ASD task force) or more permanent (a standing committee focused on ASD or a subcommittee of a governor's council on disabilities); they may address ASD more broadly or focus on a specific issue (e.g., ASD screening and diagnosis); they may be limited to the actions of a single government agency or seek to build interdisciplinary or cross-agency collaboration; and the policy may seek or require the involvement of advocates or advocacy groups. The products of such policy can also vary widely: from broad position statements to a published report with specific practice recommendations and from forming an advisory committee to identifying a person within a government agency to be responsible for coordinating information and advocacy to creating a new government agency with specific responsibilities to oversee services, training, research, and/or policy. Many of these steps are evident in the evolution of ASD policy in Pennsylvania: a cross-agency task force that included many advocates generated a report with very specific policy recommendations and that resulted in the creation of a new government bureau with specific responsibilities for overseeing services, training, research, and policy development within in a state department (Wexler et al. 2013).

Other efforts have been undertaken at the federal level. Many federal departments have convened workgroups or committees to gather

information and develop policy. For example, the Interagency Autism Coordinating Committee within the US Department of Health and Human Services (iacc.hhs.gov), first authorized under the Children's Health Act of 2000 and then reauthorized and broadened under the Combating Autism Act of 2006, produces detailed reports intended to inform and coordinate federal agency policies. The Learn the Signs Act Early (LTSAE) initiative undertaken by the Centers for Disease Control (<http://www.cdc.gov/ncbddd/actearly/index.html>) is perhaps the most coordinated federal effort to date. Focusing on early identification of ASD and related disabilities, LTSAE has led to the development of detailed publications for professionals and the general public, and facilitated the development of state-level teams to disseminate training and information, and to engage the full range of stakeholders in the creation of state plans (Peacock et al. 2013). In many cases, such federal efforts solicit the involvement of non-governmental organizations through grants and contracts: for example, the state summits convened through LTSAE were coordinated through a contract by the Centers for Disease Control and Prevention with the Association of University Centers on Disabilities, while the National Autism Resource and Information Center was created through a grant to The Arc of the United States (www.autismnow.org).

ASD Services

With the exception of initiatives related to health insurance (see below), the majority of social policies intended to directly increase services have been undertaken not at the state or national level, but at the local level (Doehring 2013). These policies include decisions made by schools and early intervention programs regarding the amount of services provided to children with ASD, the emphasis on particular programs and approaches such as applied behavior analysis, and the creation of ASD-specific positions or intervention programs. Such policies are adopted haphazardly across the United States, sometimes through the efforts of advocates, and other times through the decision of an individual school district or county leader. Given the costs associated with increased

and improved services, and the seminal role of parent advocates, it is not surprising that such policy changes are more likely to have been enacted in more affluent suburban regions. While a number of state-level initiatives targeting training to, consultation with, and oversight of service providers have been undertaken (see below) few state-level programs directly increase services, except perhaps for comprehensive centers established in West Virginia (Becker-Cottrill 2013) and Delaware (Doeiring and Winterling 2013), and other programs focussed on specific statewide needs (Carbone et al. 2013).

Current social policies with the greatest likelihood of directly increasing the amount and availability of services are those related to insurance reform, although the impact is likely to vary significantly from state to state. With the support of organizations such as Autism Speaks, advocacy groups have successfully lobbied for the inclusion of mandated benefits related to the provision of applied behavior analysis in insurance regulations, beginning with Indiana in 2001 (at the time of writing, 34 states had enacted such reforms). While the exact legislation varies from state to state, it can include provisions for more than \$30 000 of direct services and supports in the home and community annually, but is often restricted to a subset of health insurance plans, may exclude adults, does not address education-based services, depends on the availability of qualified providers, and may require that parents navigate often-confusing insurance procedures. Advocates lobbied for inclusion of similar benefits in the Affordable Care Act (ACA), passed in 2010 to extend health care benefits to all Americans. In addition to extending services important to people with ASD and traditionally included in health care (prescription drug coverage and so on), ACA includes ASD screening at 18 and 24 months as well as “habilitative” services and “behavioral health care” as required benefits in any insurance sold within the ACA “marketplace.” At the time of writing, the impact of these changes depends on state-by-state interpretation of key statutes of the law and its associated regulations.

ASD Training

In contrast to ASD services, a number of policies have been enacted at the state and national level to address training. The National Professional Development Center on Autism Spectrum Disorders was a consortium of university-based centers, funded by the Office of Special Education Programs (OSEP) of the US Department of Education, to build training capacity state by state within the public school system (Cox et al. 2013). A number of states have undertaken training and consultation initiatives targeting educators (Stickle and Hoffmeier 2013; Pratt 2013; Wexler et al. 2013). The network of programs in Leadership Education in Neurodevelopmental and related Disorders (LEND) added autism-specific training to its curriculum targeting a broad range of graduate-level trainees in health and education. At the time of writing, the network included 43 LEND programs across 37 states and was supported through grants provided through the Maternal Child Health Bureau.

Other policy initiatives seek to establish general standards for training and certification. For example, a set of national standards for teachers of children with autism was developed by the Network of Autism Training and Technical Assistance Programs (an affiliate of Autism Society of America) in 2009, and subsequently endorsed by National Council for Accreditation of Teacher Education (NCATE) and the Council for Exceptional Children. Many states have adopted Autism Teacher endorsements that formally recognize a postgraduate program of specialized training, while states such as Delaware require that all public school teachers of children with autism complete a postgraduate certificate from an accredited program. Many states have also moved to formally recognize Board Certified Behavior Analysts (BCBAs) by adopting the licensure requirement of the Behavior Analysis Certification Board (BACB). Autism Insurance regulations adopted in some states have stipulated that only behavior analysis services supervised by a BCBA are eligible for reimbursement, even though training in autism is not required for BCBAs.

ASD Practice Standards

Other social policies with important implications for ASD training and services center on formal endorsement of written standards for specific assessment and intervention practices, enacted by professional and governmental entities. National organizations of physicians and their subspecialties have endorsed a variety of policy or consensus statements regarding specific practices, including the identification and management of autism (Johnson et al. 2007; Myers et al. 2007), the identification and management of gastrointestinal disorders in people with ASD (Buie et al. 2010), and recommending against the use of auditory integration training and facilitated communication (American Academy of Pediatrics 1998)

Other federally funded initiatives have sought to establish standards of practice, although the relevance to social policy cannot be clearly established because the path to implementation is often unclear. For example, the National Research Council reviewed the available research and developed a broad set of recommendations regarding the education of children with ASD (Committee on Educational Interventions for Children with Autism 2001). The aforementioned National Professional Development Center on Autism Spectrum Disorders (NPDC) conducted systematic reviews of the outcome research to establish a list of evidence based practices (EBP) (Cox et al. 2013) had constituted the backbone of the NPDC's program of training. While the work of both groups has been widely cited, these reviewers know of no public entities responsible for delivering services that made a formal commitment to require that their services and training rely on these recommendations.

ASD Research

A wide range of national research initiatives related to ASD have been undertaken, although many – if not the vast majority – of these did not contribute directly and immediately to improved practices, and so their relevance to social policy is unclear. For example, different federally funded autism programs – the Collaborative Programs for

Excellence in Autism initiated in 1997, and the Studies to Advance Autism Research and Treatment initiated in 2000 – were merged and expanded in the Autism Centers of Excellence Programs through the Combating Autism Act. The vast majority of projects have focused, however, on the causes, characteristics, and developmental trajectory of ASD, as opposed to validating and promoting the widespread adoption of effective treatments. The Autism Treatment Networks originally established by Autism Speaks, and then repackaged as the Autism Intervention Research Network on Physical Health (AIR-P) with support from the Health Resources Services Agency in 2007, has sought to develop recommendations and toolkits for practitioners. The AIR-P may represent the public program with the greatest potential to improve community-based practice, but the impact has ultimately been limited by the lack of any formal endorsement of these recommendations by a public or professional entity providing services. The reports of the ADDM network, that continue to refine estimates of prevalence, also continue to have perhaps the greatest impact of policy.

Individual states have also established other research programs intended to gather data needed to inform public policy. For example, a number of states have passed legislation to establish autism registries to, among other goals, identify the number of people in the state with ASD and who require services. It is unclear how such registries have influenced policy decisions, especially given the availability of more rigorous assessments of prevalence available through the ADDM network. Pennsylvania's efforts represent perhaps the most coordinated effort to conduct applied research to inform state policy. A census of all Pennsylvanians receiving health or education services under an ASD label revealed significant county-to-county variability in rates of actual identification or administrative prevalence, as opposed to prevalence projections derived from CDC estimates (Lawer and Mandell 2009). These discrepancies, together with a needs assessment that generated a series of reports about access to and satisfaction with services, now guide state

initiatives to develop and improve services (Wexler et al. 2013).

Comprehensive Reform

The majority of policies are enacted in relative isolation from one another, addressing a specific element (e.g., services or training or research or further policy development) perhaps within a specific domain (health or education or community services). Occasionally, policies are enacted that intended to foment more comprehensive reforms. For example, the Combating Autism Act (CAA) signed into law in 2006 (PL 109-416) and authorizing almost \$1 billion in additional spending on autism represented the largest and most comprehensive legislation focused on autism to date. CAA expanded a wide range of programs through a variety of federal agencies: research and coordination at the National Institutes of Health (NIH), ASD awareness and surveillance activities at the Centers for Disease Control and Prevention (CDC), and training of health professionals within the Health Resources Services Administration to screen, diagnose (or rule out), and provide ASD interventions. CAA also promoted the development of programs to inform the public about ASD (including the National Autism Resource and Information Center), and redefined and enhanced the mandate of the Interagency Autism Coordinating Committee.

Future Directions

Social policy with respect to ASD is constantly evolving, with increased understanding of the needs of the population, changes in government leaders and structures, and shifting societal values.

DSM-V

While the DSM-V allows a DSM-IV diagnosis of ASD to be carried forward, it is unclear whether all individuals previously eligible for a diagnosis of Asperger syndrome or PDD-NOS under the DSM-IV would merit a DSM-V diagnosis of ASD. This may require changes to social policies to accommodate the needs of individuals rendered

ineligible for specialized services and supports under this revised nomenclature.

Improving and Increasing Services at the Local Level

Despite decades of research and advocacy, huge gaps persist between social policy at the national level and day-to-day practice at the local level. National programs like LEND, Learn the Signs Act Early, and the National Professional Development Center demonstrate innovations in raising awareness and training professionals, but the amount, accessibility, and quality of services still vary tremendously from one community to another, with traditionally underserved populations being especially vulnerable. Though some advocates and policymakers have sought to prioritize more comprehensive reforms in services, there is currently little chance for new federal programs addressing the services and supports needs of those on the spectrum, given the current national focus on reducing the deficit and the size of the federal government. Regardless, any substantial changes to services at the local level would have to be carefully coordinated with changes at the state and national level in training and policy, and guided by research focused on implementation. (Doehring 2013)

The Identity of the ASD Community

It also remains unclear whether the autism community can or should speak with a single voice. Perhaps some philosophical differences are inevitable given the breadth of the autism spectrum; some persons with ASD require intensive, life-long services and supports associated with their developmental disabilities; and others who are able to live independently seek recognition and respect for the ways they are different. These differences often translate into competing priorities, with some seeking more research on prevention or intensive treatment and others focused more on civil rights and services and supports for adults. Despite efforts to differentiate ASD from other disabilities, individuals with ASD and intellectual disability or ID may in fact have more in common with those whose ID uncomplicated by ASD, than those with ASD but not ID (Doehring 2013). This may indicate potential

benefits from an alliance with the community of those with developmental disabilities. Interest and attention has also shifted over the past 5–10 years to encompass the needs and services required for adults with ASD, as the children identified in the “epidemic” beginning in the 1990s grow into adults who can no longer benefit from educational entitlements.

USA and Autism

Historical Background

There is a long and distinguished (and complex) history of work on research, clinical care, and training on autism and related disorders in the USA. Of course, the starting point for this discussion is the land breaking description, in 1943, of autism by Leo Kanner. His remarkably enduring, phenomenologically based description of autism highlighted key vulnerabilities in the area of social interaction and unusual environmental responsiveness and became the conceptual basis for all subsequent definitions. At the same time, it also serves to mislead research in some ways, e.g., the use of the term autism suggested a possible conduit with schizophrenia, and his observation of high levels of parental educational attainment also suggested, to some, a possible contribution of experience to psychopathology. During the 1950s in particular, the emphasis on “blaming” parents (particularly mothers) took a decidedly unfortunate turn, and only in the 1960s and particularly in the 1970s did scientific opinion begin to shift as the strong brain and genetic bases of autism began to be appreciated. The early work of the psychologist and parent, Bernard Rimland, was key in this effort (Rimland 1964) as was the work in the 1970s suggesting the validity of autism (Kolvin 1971) and its strong genetic and neurological basis (Folstein and Rutter 1977; Ornitz and Ritvo 1968) and the importance of structured treatment programs (Bartak and Rutter 1973). The pioneering work on the neurochemistry of autism (specifically on serotonin) by Daniel X. Freedman and colleagues was also important (Hanley et al. 1977) as was the early work on pharmacological treatment (Campbell et al. 1971). Early confusion about the

distinctiveness of autism complicated much of the early work, but a growing appreciation of its importance and validity as a condition stimulated a marked increase in research further facilitated by the official recognition of infantile autism in 1980 in the third edition of the Diagnostic and Statistical Manual (DSM-III, APA 1980).

Several other events important in the history of autism program occurred in the 1960s with the organization of the National Autism Society in the USA (parallel to the organization of a corresponding institution in the UK). This group, founded in 1965, began to take a more active role in advocacy and support for both clinical working and training as well as research (NSAC 1978). Reorganized as the Autism Society of America, this group was involved in establishing legal mandates for educational services and for legislation at the state and national levels. In addition to the ASA, a number of other parent-founded foundations and advocacy groups have become active including the National Alliance for Autism Research (NAAR), Cure Autism Now (CAN), Autism Speaks, and Autism Science Foundation. Particularly during the 1990s, a critical body of work began to be available, and federal initiatives to support research began to increase. Notable programs included the Centers of Excellence for Programs in Autism (CPEA) led through the National Institute of Child Health and Human Development by then Director Dwayne Alexander and program officer Marie Bristol-Power were succeeded by support from multiple NIH institutes. These included the Studies to Advance Autism Research and Treatment (STAART) and Autism Center of Excellence Programs. The impact of these initiatives both on research and well-trained investigators has been enormous.

The recognition of autism as a brain-based disorder with a need for structured treatment programs inspired a large body of work on behavioral and special educational interventions (Ferster 1972; Lovaas 1987). Unfortunately, schools often did not wish to provide services or felt unable to do so, and, as a result, parents were frequently involved in developing their own school programs, many of which continue to exist today – sometimes with changes in mission

and orientation over the years. This situation began to dramatically change with the advent of Public Law 94-142 and, along with other advances, has been associated with a significant change in long-term outcome (Howlin 2013).

Many of the earliest programs developed for autism have evolved over the years – often moving from center-based to more home- and community-based programs (see National Research Council 2001). The advent of programs combining behavioral and developmental approaches to treatment is particularly exciting as is the development of regional and statewide programs like Division TEACCH in North Carolina under the leadership of Eric Schopler and Gary Mesibov.

Another important historical development includes founding of the first journal devoted to autism in 1971 – the *Journal of Autism and Developmental Disorders*. Originally called the *Journal of Autism and Childhood Schizophrenia*, Leo Kanner served as the first editor. Over the years, Kanner was succeeded by Eric Schopler and Michael Rutter, then by Gary Mesibov, and most recently by Fred Volkmar. A number of other journals with varying degrees of focus on autism have now appeared, and the advent of an increasing body of peer-reviewed research has undoubtedly contributed to the significant increase in research in the field. A final important area to note has been the development of models of training for individuals working as teachers and professionals in the field. This work has aimed to increase the quality and quantity of teachers, professionals, and others knowledgeable about autism and its treatment (Volkmar et al. 1988).

Legal Issues, Mandates for Service

As noted, the passage, in 1975, of Public Law 94-142, now codified as IDEA (Individuals with Disabilities Education Act), was a watershed event in helping establish eligibility of children for school-based services. The intention of this act was to ensure that states and school districts ensure access to a free appropriate public education (FAPE) to children with disabilities of various

types, all children with disabilities (Mandlawitz 2005). Both follow-up legislation and various state and, particularly federal, judicial decisions have clarified important aspects of this mandate. It is important to note that this law differs in important respects from another statute, the Americans with Disabilities Act of 1990, a law concerned with protecting individuals with discrimination based on a disability. While this act has some relevance to children, it becomes particularly important as students transition from high school to vocational and college programs where access to service is not an automatic right (although reasonable accommodation for a disability is) (Wolff et al. 2009).

Overview of Current Treatments and Centers

The range and diversity of treatment programs and centers has increased dramatically in the past decade. As noted above, a range of programs have been developed, and a number now have substantial empirical research support with many now regarded as evidence based (Reichow et al. 2011). Over the past decade, there has been a growing awareness of the importance of peer exposure and mainstreaming in the acquisition of social skills (Tobin et al. 2012). At the same time, there has been recognition that, in some cases, more intensive behavioral and educational supports must be provided – sometimes in non-mainstream settings. Preparation of teachers and support personnel in schools has also been recognized as increasingly important (Wolery et al. 1993). As noted above, a range of models of intervention are now available and include both strongly behaviorally based programs, those that have a more developmental orientation, others that might best be described as eclectic, and, finally, some that combine aspects of multiple approaches. As with other treatments in psychology and medicine, initial results of intervention programs sometimes are the most positive and are tempered by subsequent experience as programs move from university-based clinical settings to more “real world” applications.

A recurrent tension in treatment research has been the numerous interventions that technically fall in the no established category – these include complementary and alternative treatments (Volkmar and Wiesner 2009). In some areas of intervention research, there has not been a strong tradition of carefully controlled research so information is limited (but sometimes growing). In other areas, research is minimal but treatments are promising, and in yet other instances, treatments are said to be incapable of empirical proof – this latter category is of greatest concern particularly when a child is removed from treatments with some research bare and/or enrolled in programs that entail some actual risk of direct harm to the child.

Overview of Research Directions

Most significant research programs within the country function within the context of college/university settings with a strong commitment to research and training. While there are some important obstacles to research (particularly treatment research), there has been a major expansion over the past decade with hundreds of peer-reviewed scientific papers appearing each year. Advances have been made in multiple areas including brain development and understanding of the social brain in autism (Insel and Fernald 2004; Dawson et al. 2005) of basic genetic mechanisms (State and Levitt 2011) and potential brain effects/correlates of treatment (Voos et al. 2012). Research on potential pharmacological interventions has also significantly advanced and, recently, potential interventions that might impact social disability. The multisite study of risperidone, now approved as an effective intervention for agitation and irritability in autism, is an excellent example of such work (McCracken et al. 2002). At the same time, of course, sometimes initially promising results are not replicated in subsequent studies. The dearth of intervention research, particularly focused on adults, remains a major area of concern. The support of research by both the government and by a range of foundations (including Autism Speaks, Autism Science

Foundation, and Simons Foundation) remains critically important.

Social Policy and Training

Many advances in the on-going training of providers (teachers, health-care professionals, and others) remain a top national priority. As noted above, efforts have been made to develop and implement curricula to enhance effective teaching methods in schools and classrooms (Harris et al. 2005). New approaches to training are now underway and include Internet-based services, publicly available materials, and privately produced materials. Establishing the evidence base of proposed treatments remains a priority as does the critical need for work on older individuals with autism.

Using Shaping to Increase Foods Consumed by Children with Autism

Definition

Shaping is an instructional approach that involves increasing the probability of a response through the gradual transformation of a current level of responding due to the successive approximation of a targeted class of behaviors. Shaping procedures involve the consideration of the current relevant repertoire, terminal goals, systematic approaches to the terminal goal, and maintenance (Goldiamond 1974). In the treatment of food

selectivity, shaping can be used to increase the variety or amount of food consumed. This is accomplished by providing reinforcement for the target level of food acceptance determined by considering both the present level of food acceptance and the terminal goal for acceptance and providing reinforcement contingent upon the display of the target behavior. The level of food acceptance is increased over time until the child meets the terminal goal.

Historical Background

Historically, shaping has been demonstrated to be effective both across and within response topographies. For example, Isaacs et al. (1960) shaped the eye movements of an individual diagnosed with schizophrenia to lip movements, speech sounds, and ultimately recognizable words. Wolf et al. (1964) reinforced successive approximations (i.e., touching eye glasses, picking up eye glasses, putting glasses up to face) to the end goal of wearing eye glasses in a preschooler who was in danger of losing his sight if he did not wear his glasses. Rea and Williams (2002) used shaping to increase the duration of an individual's breath holding prior to measuring exhaled carbon monoxide levels during smoking cessation treatment.

Current Knowledge

Interventions used to increase the acceptance of new foods with children with autism commonly include one or more of the following components based on learning theory: escape extinction, differential reinforcement of alternative behavior (DRA), noncontingent reinforcement, and some form of systematic exposure or antecedent intervention (Chawner et al. 2019; Silbaugh et al. 2016). Multicomponent treatment packages that include escape extinction with DRA and demand fading demonstrate effectiveness in treating food selectivity across multiple settings and with parents or therapists as implementers (Russo et al. 2019; Najdowski et al. 2010; Najdowski et al. 2003; Silbaugh et al. 2016). For example, Russo

et al. (2019) increased the variety of foods consumed across all food groups for two adolescent males with autism by providing antecedent choice for both the preferred and nonpreferred target food, implementing escape extinction of inappropriate mealtime behavior and systematically increasing the number of bites and variety of food presented in order to meet criterion for reinforcement. However, given that DRA is indicated as a preferred treatment by caregivers to treat food selectivity compared to escape extinction (Vazquez et al. 2019), it is not surprising that systematic exposure techniques such as demand fading and shaping with DRA are evaluated more often than escape extinction to increase the variety of foods consumed in children with ASD (Chawner et al. 2019). Effective shaping interventions that do not include escape extinction generally include a multistep hierarchy of graduated exposure that the child moves up as he or she meets criteria and moves down as a result of consecutive errors or engaging in refusal behaviors. Response requirements in hierarchical exposure vary from beginning with tolerating the food in the same room (Tanner and Andreone 2015) to touching the target food with the hands or lips (Hodges et al. 2017; Penrod et al. 2012) and ultimately conclude with swallowing or consuming the food. Tanner and Andreone (2015) evaluated a 12-step hierarchy with a child with food selectivity and ASD. The hierarchy gradually increased the demands over a span of 9 months from tolerating target foods in the same room to consuming the target foods and resulted in acceptance of 50 previously refused foods.

Luiselli et al. (2005) increased the amount of milk a young girl with autism drank by gradually increasing the amount she was required to drink and providing reinforcement contingent upon consumption of the liquid. Koegal et al. (2012) increased food variety in three children with autism who had selective diets by using a systematic hierarchical sequence (i.e., seven-level hierarchy) and provided individualized reinforcement upon the child's mastery of required steps. This resulted in successful expansion of food repertoire among all three participants. Hodges et al. (2017) used differential reinforcement and shaping to

increase the variety of foods accepted by children with autism who demonstrated significant feeding inflexibility. They were introduced to four new food items via hierarchical exposure, which involved systematically increasing the desired response with the food item. Following the intervention, all participants accepted the targeted foods.

Future Directions

More research is needed to identify interventions with long-term therapeutic effects, particularly for increasing variety of foods accepted (Bandini et al. 2017; Chawner et al. 2019; Koegal et al. 2012). Long-term follow-up measurements of observed treatment outcomes may help better identify treatments best suited for long-term generalized therapeutic effects. Furthermore, some individuals may continue to exhibit feeding challenges throughout the lifespan. Indeed, in one longitudinal study of children with ASD, while food refusal improved over time, there were no increases in the number of foods accepted 7 years after the initial measurement point (Bandini et al. 2017). However, in a recent systematic review, only half of the included articles ($n = 36$) included follow-up measures (Chawner et al. 2019). Without replicated demonstrations of long-term results, confidence in interventions assumed to be efficacious is weakened (Chawner et al. 2019).

There is also a need for greater evaluation of the social validity of commonly used feeding intervention components. In particular, caregiver ratings of acceptability of interventions used are necessary, because caregivers are the most common natural implementers of mealtime intervention strategies outside of treatment sessions (Vazquez et al. 2019). It is also possible that more intrusive interventions may be viewed as more acceptable if maladaptive behaviors are more severe (Vazquez et al. 2019).

Finally, because of the prevalence of multi-component interventions, future researchers may evaluate individual strategies that are effective through component analyses (Chawner et al. 2019; Najdowski et al. 2010). Component

analyses may help in identifying mechanisms of behavior change, thus streamlining the iterative intervention process (Najdowski et al. 2010). Alternatively, component analyses that may also illuminate multicomponent interventions are necessary because of the highly complex nature of feeding behaviors (Chawner et al. 2019).

Landmark Clinical, Scientific, and Professional Contributions

Having joined her PhD supervisors Neil O'Connor and Beate Hermelin in pioneering the cognitive experimental study of autism, Uta Frith's first landmark contribution was the influential "Theory of Mind" deficit account, developed and tested with fellow CDU scientist Alan Leslie and their then-PhD student, Simon Baron-Cohen. Their empirical paper showing that most children with autism failed a simple false belief test (Baron-Cohen et al. 1985) has since been cited more than 2,500 times (ISI WoS) and launched decades of research into "mentalizing." A decade later, Uta and Chris Frith were the first to use functional neuroimaging to investigate the brain basis of typical and atypical mentalizing, work for which they later received the prestigious Jean Nicod Prize.

Frith's scholarly yet accessible 1989 book, *Autism: Explaining the Enigma*, explained mentalizing deficits in autism to a wider audience and also introduced the concept of weak "central coherence", reduced global and increased local processing, revealed in superior performance on, e.g., Block design, and embedded figures tests, as shown in Frith's studies with her PhD student Amita Shah. Frith can be credited with being the

first scientist to suggest that more can be learnt about autism by studying assets than by studying deficits. In 2010 she edited a book *Autism and Talent* with past PhD student and long-time collaborator, Francesca Happé.

Frith has been a major advocate for cognitive theories of autism (and dyslexia), and her work on Causal Modelling, with John Morton, explained the importance of distinguishing levels of explanation: biological, cognitive (which includes affective), and behavioral – with environmental interplay possible at each level.

Her other notable contributions to autism science include pioneering work on education and the brain (on which she published a book, *The Learning Brain*, with Sarah-Jayne Blakemore in 2005), and autism in history (including her book on the historical case of Hugh Blair, with Rab Houston in 2000). Frith also provided the first English translation of Hans Asperger's 1944 paper, in her influential 1991 edited book, *Asperger Syndrome*

Uta Frith is also well known as a supporter of women in science, having mentored and championed many female scientists, and founded the group "Science and Shopping." She is often in the media and has presented several science programs including the BBC's Horizon.

Short Biography

Born Uta Aurnhammer in 1941 in Rockenhausen, Uta Frith grew up in Kaiserlautern, Germany. It was not until 1964 that she came to England, to the Institute of Psychiatry (IoP) in London, where she met her future husband and longtime collaborator, Chris Frith, and trained as a clinical psychologist. Originally planning a PhD on OCD, she became fascinated by autism and was delighted to find the authors of a key experimental paper she was reading were on the IoP faculty. Neil O'Connor and Beate Hermelin saw her ability at once and took her on first as a PhD student and then, even before her thesis was submitted, as a research scientist in the newly established MRC Developmental Psychology Unit. Uta remained an MRC staff scientist for more than 35 years,

helping to choose the other faculty at the subsequent MRC Cognitive Development Unit. It was at the CDU that the “Theory of Mind” deficit account of autism was conceived and tested. At the same time, Uta was at the forefront of cognitive studies of dyslexia – and she has maintained her fascination with both types of neurodiversity throughout her career.

When the CDU closed in 1998, Uta became Deputy Director of the new Institute of Cognitive Neuroscience at UCL – which neighbors the Wellcome Trust Functional Imaging Laboratory in Queen’s Square, where with Chris Frith and other colleagues she conducted the first functional neuroimaging studies of Theory of Mind. She remains an emeritus professor at UCL and is currently working on book projects with Chris, including a graphic novel about social cognition. Uta is active in public understanding of science through her media work and is a champion for gender equality in science; she is currently chair of the Royal Society’s Diversity Committee.

Apart from a vast array of landmark papers, and six books, Uta is notable for her legacy in terms of nurturing the next generations of scientists: her wide and long-standing collaborations, her generous support for students and junior colleagues, and the large and growing group of researchers who are proud to count themselves as the academic children or grandchildren of Uta Frith.

Utilitarian Attention

Jacob A. Burack¹ and Darlene Brodeur²

¹Department of Educational and Counselling Psychology, McGill University, Montreal, QC, Canada

²Department of Psychology, Acadia University, Wolfville, NS, Canada

Definition

The term “utilitarian attention” is intended to describe a style displayed by persons with autism spectrum disorders (ASD) across various components of attentional processing. The term utilitarian, based on the root word utility, implies a functional significance as would be the case when attention occurs in ways and is guided by considerations that lead to its most efficient use.

The implementation of the utilitarianism may be manifested in different ways such as the unique processing of stimuli and information that imparts meaning or guidance in a specific context or for a specific task, and by behavior that is driven by data or task requirements rather than general heuristics or information in the environment that may be of increased interest or relevance to others but incidental to the task at hand.

This notion of utilitarian attention represents an extension of earlier empirically based strength-oriented conceptualizations in the areas of visual search (O’Riordan et al. 2001), perception (O’Riordan and Plaisted 2001; Plaisted et al. 1998; Russo et al. 2012), and the iterations of the enhanced perceptual functioning model (Mottron and Burack 2001; Mottron et al. 2006), all of which stand in contrast to the more common emphasis on deficits, including in the area of attention. Thus, the essential premise of the notion of utilitarian attention is that attention is not inherently deficient among persons with ASD and may even be more efficient and effective in certain cases. Utilitarian attention is also consistent with the contemporary notion that the identification of alternative styles, biases, and ways of being is essential to understanding attentional functioning among both persons with ASD (Burack et al. 2016) and the more general population (Burack et al. 2017; Ristic and Enns 2015). In this context, the emphasis on utilitarian attention is not simply about assessing whether attentional abilities are better or worse than that which is evident among comparison groups of appropriately matched persons from the neurotypical population, but rather is meant to highlight styles, biases, and ways of attending that are unique to persons with ASD and the ways that they affect the efficiency of attention. This framework is consistent with the recently posed question about the attentional processing of persons with ASD, “How I attend - not how well do I attend” (Burack et al. 2016).

Historical Background

The term “utilitarian attention” was initially used by Brodeur et al. (2018) in the title and the interpretation of the findings of a study of visual

attention in which the participants (children) with ASD seemed to benefit from the presence of nontarget stimuli in the visual field that appeared to impede the performance of a comparison group of mental age matched typically developing participants (children). It was intended to be understood within the context of the key components of both classic and contemporary conceptualizations of attention.

The concept of attention is a longstanding and relatively intensively studied construct. Its formal scientific conceptualization is usually dated back to William James’ iconic and oft-cited observation that “Everyone knows what attention is. It is the taking possession by the mind, in clear and vivid form, of one out of what seem several simultaneously possible objects or trains of thought. Focalization, concentration, of consciousness are of its essence” (James 1890, pp. 403–404). Ironically, James’ apparent attempt to highlight the simplicity and obviousness of the concept of attention also serves to underscore that attention is far from a monolithic construct as it involves a multiplicity of components that are complexly intertwined with each other and in relation to the individual and the world around them.

Current Knowledge

As the study of attention, and its development through the life span, has grown in the century since James’ seminal observation, several foundational issues have emerged as central to any relevant framework. One, attention is not anything tangible, but rather is a construct based on observed behavior that has been forwarded to facilitate the understanding of the complex, multimodal, and ever-changing world in which we live and of the abundant dynamic information, stimuli, and events within. Two, attention is an umbrella term used for many different, albeit conceptually related, functions or components that are delineated and categorized differently across the many different conceptualizations or frameworks of attention. Three, unique developmental trajectories can be identified in relation to the demands, efficiency, and effectiveness for each of these attention components. Four, the real-

world demands on attention processes can change in meaningful ways in relation to the individual's age, environment, and transactions with the environment. Five, attentional processes have been identified within and across each of the modalities and these processes can operate in concert with and/or in competition with each other. Six, attention is captured by and directed to events, stimuli, and pieces of information that move in space and change in time. Seven, the context of the attention task influences its difficulty as other concurrent cognitive functions may either enhance or detract from performance.

In contradistinction to James' point of "Everyone knows what attention is," these points are intended to highlight the increasing levels of nuance and complexity in providing some general understanding of attention and the difficulty in articulating any single characteristic of attention that can be applied universally across the conceptualization of attention and its components for all stimuli or information, across different settings, at different developmental stages. This level of deconstruction of the notion of attention is inevitably magnified in considering its manifestation among persons with ASD for whom any type of functioning might vary considerably in relation to the vast differences within the population with regard to developmental level of functioning, level of symptomatology, and etiology. Thus, the claim for utilitarian attention is not meant as necessarily universal with regard to all components of attention nor for all persons with ASD, but rather as insight into unique, and often unexpected, findings of strengths or patterns of performance and as a framework for interpreting the biases and styles of processing displayed on certain tasks.

Although the notion of utilitarian attention among persons with ASD is recent and has not yet been tested directly, its different manifestations appear to be supported by findings from a range of studies on various components of attending. The Brodeur et al. (2018) study was designed to assess the visual filtering component of attention, which is typically depicted as the process of focusing on some stimulus or event while ignoring, or filtering, other potentially distracting non-target information in the environment. The

experimental paradigm was a flanker task, commonly used in studies of filtering, in which participants are required to respond to the identity of a target stimulus that is presented between flanker stimuli which, depending on their physical attributes and location in relation to the target stimulus, appear to serve as distractors that can impede performance as indicated by reaction times (RTs) and/or error rates. In their task that was administered to a group of children with ASD and a group of typically developing (TD) children matched at a mental age (MA) level of approximately 7.4 years, Brodeur et al. instituted both spatial and temporal manipulations. They presented the target stimulus in the middle of a computer screen and flanked it with nontarget stimuli (i.e., flankers) that were presented 180° to the right or the left of the target at three different spatial distances (2.32, 6.92, and 13.78 visual degrees) and, in the most novel aspect of the paradigm, with four conditions of temporal delays (0, 150, 300, and 450 ms) in the onset between the presentation of the target and the flankers. With regard to the spatial effect, the TD children showed the expected distracting effects as their RTs were slower in the conditions in which the flankers were at closer proximity to the target, but apparently unaffected in the condition in which the distractors were considerably more distant from the target. With regard to the temporal effect, the performance of these participants appeared to be unaffected by the presence or lengths of the temporal delays between the onset of the target and flankers. In comparison, the participants with ASD displayed a quite different pattern of performance. They showed no spatial effect in relation to distance with similar RTs for the three conditions of flanker distances, but displayed effects of the temporal relationship with faster RTs in the conditions in which the distractors appeared either simultaneously with the target or very briefly after it (150 ms as opposed to 300 or 450 ms).

Based on these findings, Brodeur et al. concluded that the children with ASD were able to utilize the flankers in the simultaneous and 150 ms conditions in such a way as to create a window of attention that facilitated their focus on the target, thereby speeding up their RTs. Thus, rather than

being distracted by the flanker stimuli, as appeared to be the case with the TD participants, the participants with ASD appeared to adaptively utilize the spatial location of the flankers as cues to help focus attention on the target stimulus, regardless of the distance of the flankers from the target when the target and flanker stimuli were closely linked temporally. This apparently unique pattern, in which the participants with ASD were able to benefit from the flanker stimuli, was interpreted by Brodeur et al. as indicative of utilitarian attention.

Brodeur et al.'s case for utilitarian attention based on the ability to use the flankers as cues is consistent with earlier findings by Burack (1994) on another filtering task that also involved a flanker paradigm. In that study, Burack (1994) found that only a group of low functioning persons with autism, as compared to two groups of mental age (MA)-matched individuals with intellectual disability and a group of MA-matched typically developing persons, showed enhanced RTs in identifying a target stimulus that appeared in the middle of the screen in conditions with no distractors when a visual window was superimposed around the middle of a screen. Other evidence from the study indicated that the persons with ASD were generally less efficient than the other groups in modulating, or adjusting, the attentional lens to focus on the target as their focus of attention was distributed more broadly and extended out farther from the target. Thus, as the presence of a window was only associated with improvements in their performance, the persons with ASD seemed to have imposed a utilitarian approach to attending by using the window as an external facilitator to effectively narrow the lens, or width of spatial attention, a task which otherwise seemed to be difficult for them. Within this context, the findings from the Brodeur et al. study appear to provide further evidence of the facilitative effects of a spatial framing cue even when comprised of discrete stimuli, such as the flankers, rather than a complete framing of the target. This all suggests that one aspect of the utilitarianism in attention might involve some way of cognitively interpreting, processing, or manipulating nontarget stimuli in the environment

such that they uniquely serve as beneficial cues to persons with ASD, although they may be deleterious to the performance of other persons.

Iarocci et al. (2006) suggested a second type of utilitarian attention when they concluded that the children with high functioning ASD showed a more "data -driven" approach as compared to both verbal and nonverbal MA-matched groups of typically developing children in their two-experiment study of visual search for global and local stimuli. In the first experiment, the children with ASD were as able as the TD participants to access targets at either level of visual structure on a visual search task in which the effects of structural bias were manipulated to favor access to either the local or global targets. However, group differences were noted in the second experiment in which a structural global bias was pitted against an implicit task bias that favored the local level, with the probabilities that target would appear at the local level varying from unlikely (30%) to likely (70%) within the blocks of trials. The children with ASD displayed similar levels of sensitivity to the biasing manipulations for both the global and local targets, while also showing the smallest task independent bias in favor of global targets. Iarocci et al. argued that the sensitivity to bias shown by children in this experiment cannot be interpreted as a response bias, as the biasing manipulation only affected the likelihood that the target stimulus would appear at either global or local level, and did not affect the likelihood of the actual response. Rather, Iarocci et al. concluded that the sensitivity to bias shown by the children with autism indicated a unique enhanced ability to overcome, or ignore, task independent biases to either the local or the global level of processing that typically interfere with the performance of other persons.

In another study in which the findings that can be interpreted as reflecting "data-driven" behavior, Ristic et al. (2005) challenged the prevailing notion that persons with ASD were unable, or at least severely impaired in the ability, to follow eye gaze. In doing so, they contrasted the notion of the "social power" of eye gaze in the everyday functioning of typically developing (TD) persons that leads to the inherent following of eye movement

in all faces, even clearly unrealistic faces such as schematic ones, with a pattern of responding among persons with ASD both that indicated an ability to follow and make meaning of eye gaze and that is inherently more efficient, or cost effective, as it is only used when the data from the environment suggests its utility.

Ristic et al. (2005) presented high functioning adolescents and young adults with ASD and a group of chronological age- and IQ-matched typically developing participants with a centrally presented schematic face whose pupils could move from side to side to cue the location of a target presented to its right or left. This comparison involved two conditions – a nonpredictive condition in which the cue only predicted the location of the target on 50% of trials and a predictive gaze condition in which the cue direction predicted the location of the target 80% of the time. As expected both from previous evidence indicating the salience of eyes in the general population and from the narrative of eye gaze following deficits among persons with ASD, the TD participants, but not those with ASD, displayed faster RTs for congruent cue-target trials than for incongruent cue-target trials in the nonpredictive condition. However, any support for a deficit was dispelled in the predictive condition on which the participants with ASD, like the TD participants, displayed faster RTs for congruent cue-target trials than for incongruent cue-target trials in the predictive condition, suggesting that both groups used the cue in an advantageous way to guide their anticipation of where the target would appear. These findings indicate an essential difference in the utility of attention between persons with ASD and their neurotypical peers, whose attending appeared to be governed by a heuristic that prioritizes social information. Whereas eye gaze automatically captured the attention of the TD participants regardless of whether it provided any information about the subsequent location of a target, the participants with ASD appeared to display a more utilitarian approach to attending by only following eye gaze in situations in which it was useful to successful task completion.

In a similar study in which eye-tracking technology was used to monitor attention to eyes and faces in both an object search and gaze-reading task, Del Bianco et al. (2018) found that proportional looking time to faces was task-dependent among a group of adults with ASD but not for a comparison group of TD adults. Although the groups displayed similar proportions of first fixations to the faces, only the participants with ASD looked at faces more when it was most beneficial to do so; in the gaze-reading task. Del Bianco et al. speculated that the performance of the persons with ASD might reflect less efficient attending, although the increased task-dependent behavior certainly suggests a utilitarian approach to attending, especially in the context of the focus on eyes and faces which is so often cited as a source of deficit among persons with ASD.

Joosten et al. (2016) similarly examined gaze and visual search strategies in children with ASD and neurotypical children using a video of a magic trick as the to-be-attended event. Eye movements were recorded toward both the gaze of the magician and other objects in the video during the initial viewing of the trick, and again after the participants were informed that magicians use gaze-aversion tactics to draw the audience's attention away from specific areas to ensure the success of the trick. Consistent with the argument that the attention of persons with ASD is less governed by general heuristics (e.g., social information prioritization), the a priori attention of the neurotypical children was characterized by a bias to attend to gaze, whereas the children with ASD showed no such search pattern as they showed little preference for eyes or gaze-cued stimuli. However, after learning about the magician's gaze aversion tactic, both groups adjusted their attentional style to look less at eyes and gaze-cued objects. In addition to highlighting that persons with ASD, like TD persons, can use instructions to adopt an optimal attention strategy to increase the likelihood of successful task performance, these findings are further support for the notion that the attention of persons with ASD is less influenced than that of TD persons by social stimuli that have been shown to impede task performance in some circumstances.

Future Directions

As is the case with any construct, identifying the source of utilitarian attention, which is found among at least some persons with ASD on at least some types of tasks, is a conceptual exercise that can involve many possibilities. The enhanced perceptual functioning model (Mottron and Burack 2001; Mottron et al. 2006), based on extensive evidence of superior visual and auditory sensory capacity among persons with ASD, provides one foundation for understanding why the attentional processing of persons with ASD might be particularly utilitarian. As perceptual processes are thought to temporally precede those of attention and other aspects of cognition, faster or better perception might pave the way for more economical or efficient “downstream” processing, including that of attention. Alternatively, Pellicano and Burr (2012) offer a Bayesian account in which perception is based on the interplay between basic sensory capacities and prior probabilities, based on prior knowledge about the world. Among persons with ASD, perceptual input may be interpreted more accurately due to attenuated Bayesian priors, referred to as “hypopriors,” that lead to perception that is less biased by accrued experiences with the perceptual environment. Such a model is consistent with utilitarian attention in that perception, presumably related to attention components, is governed less by heuristics and more by data-driven or current, task specific, utilitarian information.

Commensurate with contemporary perspectives in which the emphasis is on individual styles, experiences, motivation, background knowledge, needs, and interests that affect attention with specific information in particular contexts (Burack et al. 2016; Krauzlis et al. 2014; Ristic and Enns 2015), the hypothesized link between engineering and ASD and the related notion that persons with ASD show advanced levels of folk physics (Baron-Cohen et al. 1997; Wheelwright and Baron-Cohen 1998) suggest that persons with ASD might be uniquely able to benefit from the abilities both to construct facilitative visual cues and efficiently utilize task-relevant data in the

environment while ignoring other information or events that distract others.

A first step in future scholarship would be to revisit and reassess key findings from the literature on attention among persons with ASD, especially cases of particular strengths, in order to identify other examples of attending that can be interpreted as utilitarian. These instances should be examined within the contexts of the various theoretical perspectives that might explain utilitarian attention. The information from this conceptual exercise will inform the quest to delineate the environmental settings, attentional tasks, and individual characteristics that are most likely to elicit utilitarian attention. With this type of information, researchers and practitioners will be able to facilitate the development of educational and vocational opportunities for persons with ASD that allow them to benefit from their particularly unique ways of attending to and processing information in the world around them.

Utility of Repeated Autism Screening at 18 and 24 Months

Definition

Importance of repeated screening for autism spectrum disorder (ASD), following a negative (i.e., no risk) screening, in order to maximize identification of toddlers with ASD and other neurodevelopmental disorders.

Historical Background

Early diagnosis of ASD, followed by targeted intensive intervention services, improves children’s outcomes (Anderson et al. 2014; MacDonald et al. 2014; Rogers and Vismara 2008). Despite the fact that ASD symptoms typically emerge within the first 1–2 years of life and caregivers often report concerns early in their children’s development (Crais et al. 2014; Hazlett et al. 2017; Maestro et al. 2005; Ozonoff et al. 2010; Zwaigenbaum

et al. 2005), a large proportion of children are not diagnosed until they are 3 or 4 years old (Centers for Disease Control and Prevention [CDC], 2018). Routine screening at well-child care visits reduces children's age at diagnosis and mitigates discrepancies in age at diagnosis for children of various racial and socioeconomic status backgrounds (Herlihy et al. 2014). Accordingly, the American Academy of Pediatrics (AAP) recommends screening all children for ASD at 18 and 24 months (Duby et al. 2006; Johnson and Myers 2007). Despite the recommendation to screen at both time points, and the clear benefits of screening, many pediatricians do not practice repeated screening. Indeed, barriers including a lack of time and limited staff to implement screening procedures prohibit screening in many pediatrician practices and are likely to make repeated screening particularly challenging (Arunyanart et al. 2012; Zuckerman et al. 2013). As well, caregivers may have reservations about repeating screening after their children recently screened negative. As data increasingly supports the ability to diagnose ASD earlier (Pierce et al. 2019), as well as the importance of early detection and intervention, it is important to identify the optimal screening time points that enable detection of the largest number of children who would benefit from intervention.

Current Knowledge

To our knowledge, only one manuscript has evaluated the utility of the AAP's recommendation to screen for ASD at 18 and 24 months (Dai et al. 2019). However, researchers have compared the benefits of 18- and 24-month screening as well as the positive predictive value (PPV) of screening at each age.

Symptoms of ASD typically emerge by 18 months, and a diagnosis at that age is considered stable (Ozonoff et al. 2015). In light of literature suggesting the importance of starting intervention as early as possible, during a time of brain plasticity, the AAP encourages routine screening for ASD when children are 18 months of age (Duby et al. 2006; Johnson and Myers 2007). The Modified Checklist for Autism in

Toddlers, Revised, with Follow-Up (M-CHAT-R/F) is the most widely used screener for ASD, has been translated to over 40 languages, and is recommended by the AAP. It is validated for use in children as young as 16 months (Robins et al. 2014).

Still, approximately 20–40% of children with ASD appear to either develop typically or exhibit very mild symptoms until their second year of life, but then experience either a regression of skills or a later emergence of ASD symptoms (Barton et al. 2012; Gupta et al. 2007). In light of this developmental trajectory, these children would not be detected by 18-month screening. Therefore, the AAP encourages repeated screening at 24 months, in order to increase the likelihood of identifying children who were missed by an earlier screening. Indeed, the M-CHAT-R/F PPV is stronger at 24 months relative to 18 months, particularly for children who are drawn from a general population (i.e., low-risk) sample (Pandey et al. 2008; Sturmer et al. 2017).

Caregivers and providers may be reluctant to re-screen children who previously screened negative. However, recent research suggests that 24-month screening is essential to identify children who were missed by an earlier screening. Specifically, a study of 7781 participants who screened negative on the M-CHAT(–R)/F at 18 months, and were rescreened at 24 months, found that 0.4% ($n = 32$) screened positive on the M-CHAT(–R)/F at 24 months (Dai et al. 2019). Twenty of those “at-risk” children attended a diagnostic evaluation, and, of those, 80% ($n = 16$) received a developmental diagnosis (50% ASD ($n = 10$), 30% ($n = 6$) other developmental disorder) warranting intervention. Children who received an ASD diagnosis based on their positive 24-month screening, after having a negative 18-month screening, did not differ on demographics (gender, race, ethnicity, maternal education, or annual income) nor overall developmental functioning, from children who received an ASD diagnosis based on a positive 18-month screening (Dai et al. 2019).

Although only 0.4% of children screened positive at 24 months after screening negative at 18 months, the majority of children who attended

an evaluation as a result of their repeated screening met criteria for a developmental diagnosis. The opportunity to identify additional children who will benefit from early intervention services, in our view, outweighs the risks and possible inconveniences of executing this repeated ASD screening procedure. Thus, Dai et al.'s (2019) results support the AAP's recommendation to screen for ASD at 18 and 24 months in order to facilitate early referral to intervention services while increasing the likelihood of identifying children who were missed by an earlier screener.

Future Directions

The growing emphasis on early diagnosis and intervention underscores the need to determine the optimal ages for ASD screening. Given that barriers are preventing some practices from following AAP recommendations of repeated screening, it is critical for research on the utility of repeated screening to inform clinical practice. Since only one study has evaluated the utility of repeated screening at 18 and 24 months, additional research is needed to replicate results of Dai et al. (2019) with a larger sample of children who screen negative at 18 months and then are diagnosed with ASD following a positive 24-month screening.

Additionally, the AAP's recommendation for screening at 18 and 24 months was made before researchers demonstrated the ability to reliably diagnose ASD within the first year of life. Accordingly, additional research is warranted in order to determine whether 18 and 24 months are the best ages for screening, or if repeated screening at other ages enables detection of a greater number of children at risk.

Finally, the advance of technology enables the M-CHAT-R/F to be administered online. This saves time for pediatricians and may reduce the burden of repeated screening. However, future research is necessary to compare the sensitivity and specificity of the M-CHAT-R/F when it is administered electronically, compared to paper screening followed by a phone interview.

Although there are barriers to routine screening, its utility in helping to detect children with

ASD, reduce the age of diagnosis, and decrease racial disparities in age at diagnosis makes it a critical component of well-child care visits and developmental care. Accordingly, pediatricians are encouraged to continue to screen for ASD during well-child care visits, even if children previously screened negative. Additionally, it is important to continue to encourage caregivers to complete ASD screeners and to follow through on recommendations for evaluations, when warranted.

Uzgiris-Hunt Ordinal Scales of Infant Development

Suzanne Macari

Yale Child Study Center, New Haven, CT, USA

Description

The Uzgiris-Hunt Ordinal Scales of Psychological Development (U-H Scales; Uzgiris and Hunt 1975) are a set of six scales of cognitive development designed for infants from 1 to 24 months of age. Scales were inspired by the work of Piaget (see entry ► “[Piagetian Stages](#)”) and thus are grounded in the theory that development is an “epigenetic process of evolving new, more complex, hierarchical levels of organization in intellect and motivation” (Uzgiris and Hunt, p. 47). The Scales include: Scale I: The Development of Visual Pursuit and the Permanence of Objects, Scale II: The Development of Means for Obtaining Desired Environmental Events, Scale IIIa: The Development of Vocal Imitation, Scale IIIb: The Development of Gestural Imitation, Scale IV: The Development of Operational Causality, Scale V: The Construction of Object Relations in Space, and Scale VI: The Development of Schemes for Relating to Objects.

Historical Background

Deriving from Piaget’s theory of cognitive development in the first 2 years of life (see entry ► “[Sensorimotor Development](#)”), the Uzgiris-Hunt Ordinal Scales of Psychological

Development (Uzgiris and Hunt 1975; hereafter referred to as U-H Scales) were developed as an alternative to contemporaneous infant developmental tests such as the Bayley or the Gesell. Uzgiris and Hunt argued that those tests, simply downward extensions of intelligence tests devised for older children and adults, reflected particular assumptions regarding development of intelligence in infancy. These assumptions included the following: that development in infancy reflects a unitary process ("general intelligence"; Spearman 1904); that individual differences in intelligence are synonymous with differential rates of achievement in relation to chronological age, in other words, that developmental quotient (DQ) is the precursor to IQ and continuous with it; and that developmental skills evolve incrementally, without regard to relationships among achievements or to the possibility of a hierarchical progression (Uzgiris and Hunt 1975). (Although the notion of age-referenced norms was anathema to the authors, because of wider interest, ages at which most infants in the original sample passed individual items are listed in the manual. Indeed, the size of the original sample would preclude the use of the suggested ages as true age norms.)

To challenge each of these assumptions, the authors developed the U-H Scales. First, based on Piagetian concepts, they designed six separate scales that were thought to represent "relatively independent branches" (Uzgiris and Hunt 1975, p. 15) of ability. This was a novel idea in infant assessment at that time; for example, the Bayley Scales had only a few years earlier been divided into a Mental Scale and a Motor Scale. Second, achievements in each domain were proposed to follow a consistent order, yet without being linked to a particular chronological age. From emerging research on the effects of deprivation (e.g., orphanage settings; Provence and Lipton 1962) as well as enrichment (e.g., nursery schools; Skeels et al. 1938) on development, Uzgiris and Hunt noted the critical role of the environment and thus the reduced importance of chronological age in intellectual ability. Thus, the authors intended to dissociate the measurement of intelligence from age and thus from an *a priori* rate of development. Taken to support this view was the finding that

infant DQs were not predictive of IQs in adolescence and adulthood (see Hunt 1961) despite having high split-half reliability as well as high test-retest reliability. Finally, the scales were constructed such that each item built directly on the accomplishments of the previous items. And once again, the Scales were rooted firmly in Piagetian concepts, the authors being strongly influenced by his previous scientific endeavors as a biologist: "We have also presumed that this hierarchical organization of abilities and motives consists of coordinations and differentiations among the several sensorimotor organizations already present at birth, and that progress toward the symbolic representations and regulations comprising competence and intelligence undergoes an epigenetic development analogous to the embryonic development of organ structures from the single cell constituting the fertilized ovum" (Uzgiris and Hunt 1975, p. 15). This notion of the coordination of progressively more complex systems into a hierarchical organization is illustrated by the following description of how basic actions develop into goal-directed activity: "At the simplest level, visual following over wide arcs depends upon a coordination of eye movements with head movements. At a somewhat more complex level comes the sensorimotor coordination of Piaget's second sensorimotor stage. Here, arm movements and grasping become coordinated with looking in the visually-directed reaching...and looking becomes coordinated with listening as things heard become something to look at in the behavior of auditory localization. Here, also, vocalization becomes coordinated with listening as the infant begins to recognize repeatedly encountered sounds and to manifest pseudo-imitation of familiar vocal patterns. During the third and fourth stages, according to Piaget's observations, these first habitual coordinations become coordinated at a new hierarchical level in various means-ends relationships" (Uzgiris and Hunt 1975, p. 32).

In addition to being able to measure development of infants along these six dimensions (rates of which were anticipated to be relatively independent) and compare them to each other, the authors expected that other researchers would

conduct the necessary studies to provide age norms. A further goal was to develop a tool that would facilitate research on the influence of various kinds of circumstances (i.e., child-rearing situations) on development of the various skills contained in the Scales. Finally, the authors foresaw utility in the U-H Scales to measure rates of change as well as guide efforts of intervention programs for young children.

Development of the Instrument

Piaget's manuscripts with their rich and detailed descriptions of his own infants' behavior offered a wealth of examples upon which an assessment tool could be based, the authors recognized. Their goal was to draw from these many examples and arrange them in order, both items that required eliciting *situations* as well as those that were simply observations of spontaneous behavior given a set of toys. From the volumes *The Origins of Intelligence in Children* (Piaget 1936) and *The Construction of Reality in the Child* (Piaget 1937), the authors selected a number of eliciting situations that could be reproduced in a lab setting within a brief period of time. In addition, they compiled *critical actions* associated with each eliciting situation, actions which were proposed to mean that an infant had attained a specific milestone of functioning in each domain of development. Thus began a phase of exploratory testing, inter-rater reliability, and revision that included samples of infants from 1 to 24 months of age. The first sample included 42 infants, the second included 23, and the final phase of study tested 84 infants. The final revision of the assessment was comprised of 73 eliciting situations across six scales: Scale I: The Development of Visual Pursuit and the Permanence of Objects; Scale II: The Development of Means for Obtaining Desired Environmental Events; Scale IIIa: The Development of Vocal Imitation; Scale IIIb: The Development of Gestural Imitation; Scale IV: The Development of Operational Causality; Scale V: The Construction of Object Relations in Space; and Scale VI: The Development of Schemes for Relating to Objects. Notably, the scales were constructed such that quality of performance could be documented, rather than using

the "pass/fail" criterion typical of many assessment measures. Instead, several alternative responses are listed in addition to the *critical actions* (responses that qualified as passing a given level of functioning) so that various types of "failures" could be recorded.

Scale I: The Development of Visual Pursuit and the Permanence of Objects

The items in this series focus on the development of the concept of objects, or, as Piaget referred to it, the construction of objects. At the beginning is the basic scheme of looking. The first step beyond basic looking is the visual pursuit of objects, which gradually progresses to permit following objects through larger and larger arcs until pursuit is completed for an arc of 180°. Later achievements include finding partially and fully hidden objects (object permanence) and then visible and invisible displacements of objects.

Scale II: The Development of Means for Obtaining Desired Environmental Events

This scale involves the actions infants engage in either to cause events or to obtain desired objects. Items range from visually directed grasping to pulling a string to obtain an object to using a stick to obtain a toy out of reach. "Increasing differentiation of actions-as-means from actions-as-ends, increasing determination of means by the envisioned end leading to subordination of means to ends, and increasing anticipation regarding the appropriateness of particular means seem to characterize progress along this sequence" (Uzgiris and Hunt 1975, p. 109).

Scale IIIa: The Development of Vocal Imitation

The beginning of the vocal imitation sequence involves cooing and recognition of the infant's own sounds and progresses to vocalizing in response to another's sounds and finally repeating new words.

Scale IIIb: The Development of Gestural Imitation
Items on this scale concern responses to the gestures of others, and the scale begins with a gestural response to a familiar gesture. Later items include imitation with objects, imitation of visible

gestures, and, finally, imitation of invisible gestures (not visible to the child, e.g., tapping one's own head or clucking one's tongue).

Scale IV: The Development of Operational Causality

The beginnings of comprehension of causality involve repeating actions that result in an interesting spectacle. As this ability develops, the infant will hand a spinning toy back to the examiner after a demonstration, then attempt to activate it himself/herself, and finally will attempt to activate novel objects not yet demonstrated.

Scale V: The Construction of Object Relations in Space

This series focuses on development of implicit understanding of and construction of object relations in space. Early items include accurately localizing the source of sounds, reconstructing the trajectory of rapidly falling objects, recognizing rotation of a three-dimensional object in space, and building a tower of blocks.

Scale VI: The Development of Schemes for Relating to Objects

The steps in this sequence basically describe the early development of play with toys and objects prior to representational (pretend) play. Beginning with simple mouthing and visual inspection and ending with naming objects, several steps in between include actions observed in the first year of life: simple manipulation such as hitting, shaking, dropping, and throwing, followed by so-called *socially instigated* behaviors such as showing and functional play ("indicating appreciation of their usual function"; Uzgiris and Hunt 1987, p. 124).

Clinical Uses

In a follow-up volume, Uzgiris and Hunt (1987) listed 137 research papers that had employed the U-H Scales to date, either in part or in its entirety. Several chapters in the volume were devoted to major areas of inquiry using the Scales, including measurement of progress in early intervention

studies (see Seibert 1987), and developmental assessment of children with mental retardation (Curcio and Houlihan 1987; Kahn 1987), Down Syndrome (Cicchetti and Mans-Wagener 1987), and motor impairments (Robinson and Rosenberg 1987).

As had been done previously in the context of mental retardation/intellectual disability by a host of researchers, measurement of sensorimotor development in autism was first undertaken in order to assess intellectual functioning in severely affected nonverbal children (Curcio 1978). The U-H Scales had recently been published, and was the instrument of choice for many researchers studying cognitive development in children with autism. The resulting studies reported no deficits in children with autism in most areas of sensorimotor development compared to mental-age-matched peers, with the notable exception of gestural imitation. Furthermore, a relative strength in object permanence skills was often observed in the children with autism (Dawson and McKissick 1984; Morgan et al. 1989; Sigman and Ungerer 1981, 1984; Wetherby and Gaines 1982). See Dunst (1980) for an attempt to provide more traditional norms for these scales.

Vaccinations and Autism

Paul A. Offit

Pediatrics, The Children's Hospital of

Definition

In 1998, Andrew Wakefield and co-workers published an article in *The Lancet* claiming that the combination measles-mumps-rubella (MMR) vaccine caused autism (see ► [Measles-Mumps-Rubella \(MMR\) Vaccination](#)). One year later, following a pointed directive by the United States Public Health Service and the American Academy of Pediatrics (AAP) to remove thimerosal (an ethylmercury-containing preservative) from vaccines, parents became concerned that mercury

caused autism. During the next ten years, epidemiological studies showed that both of these hypotheses were incorrect.

A few years later, the hypothesis again shifted – this time to the more diffuse and more difficult to test notion that too many vaccines given too early caused autism. While it is unethical to prospectively test children who either have or have not been vaccinated to determine differences in neurodevelopmental outcomes, one study has addressed this question retrospectively.

Michael Smith and Charles Woods took advantage of a study performed and published by William Thompson and co-workers at the Centers for Disease Control and Prevention (CDC). Thompson evaluated more than 1,000 children: first, by carefully examining the medical records of every child to determine how much mercury the child had received either prenatally in RhoGam or postnatally in vaccines and second, by prospectively administering more than 40 neurodevelopmental and psychological tests to determine if the neurological outcome could be correlated with the quantity of mercury to which the child had been exposed. Thompson found no relationship between mercury exposure and autistic spectrum disorder.

Smith and Woods mined data from the Thompson study to answer a different question. They noted that some parents had immunized their children according to the CDC/AAP schedule while others had chosen to delay, withhold, separate, or space out vaccines. Separating these children into

two groups, they found no relationship between the timing of vaccination and neurological outcome.

It is likely that the hypotheses concerning the relationship between vaccination and autism spectrum disorder will continue to shift to include adjuvants, manufacturing residuals, inactivating agents, or growth factors. All hypotheses are testable but are likely to be fruitless endeavors.

Validity

Definition

The term “validity” refers to the extent to which a concept or measurement accurately corresponds to the real world.

In psychiatry and psychology, validity is often discussed in terms of its application to psychometrics, or the study of psychological measurement. This application of the term is known as test validity, which refers to the degree to which a test measures what it claims to measure (Anastasi and Urbina 1997). Test validity is important because it determines the inferences that can be made based on the test results.

In evaluating the validity of a test, several lines of evidence can be considered to support its validity. In particular, three principal types of validity must be considered: content validity, criterion

validity, and construct validity (Lord and Corsello 2005; Sattler 2008). Content validity refers to the degree that the items on a test accurately represent the domain that the test is aiming to measure. Building content validity into a test involves careful selection of items to include, with particular focus on the thoroughness of the item sample. Criterion validity refers to the relationship between the test score and a criterion variable, such as other measures or outcomes, which has already been determined as valid. Oftentimes, a diagnosis is used as the criterion of reference, in which cases this analysis is referred to as establishing diagnostic validity. Finally, construct validity refers to the extent to which a test accurately measures a psychological construct or trait. It is evaluated by examining the correlations between the test and different measures of the same construct, as well as correlations between the test of interests and those designed to measure different constructs. Positive correlations between measures of the same domain and the absence of correlations between measures of different domains provide evidence of construct validity.

An additional use of the term in psychiatry concerns assessing the validity of diagnostic categories, or the extent to which the definition of the diagnosis accurately describes its presentation. An influential paper, published in 1970, listed five criteria for establishing the validity of psychiatric diagnoses (Robins and Guze 1970). First, the disorder must have a clear clinical description, including symptomology, demographic characteristics, and etiology. Second, laboratory tests must be conducted to further inform the clinical description. Third, the disorder of interest must be differentiated from related disorders. The fourth criterion involves conducting follow-up studies to establish the characteristic course of the disorder and provide evidence of diagnostic stability. Finally, family studies should be conducted to determine the extent to which the disorder is heritable.

Definition

Valproate is a broad spectrum anticonvulsant used to treat seizures, manic episodes, and migraines. The exact mechanism of action underlining each of the drug's clinical effects remains unclear. However, a wide range of actions have been reported to contribute to the drug's diverse effects, such as: increasing the levels of gamma-aminobutyric acid (GABA) in the brain, inhibiting voltage-gated sodium channels, reducing levels of excitatory amino acid (such as beta-hydrobutyric

acid), inhibiting calcium channels, modulating dopaminergic and serotonergic transmission, and inhibiting histone deacetylase.

Common side effects reported include tremors, confusion, fatigue, dizziness, nausea, weight gain, abdominal cramps, and abnormal liver functioning. Other potential side effects include liver damage (i.e., hepatotoxicity), metabolic and endocrine adverse effects, and teratogenicity. Prenatal exposure to valproate is associated with delayed cognitive development and congenital malformations. Additionally, prenatal use of valproate significantly increases the risk for autism spectrum disorder. Studies have shown that individuals exposed to valproate during prenatal development may be up to three times more likely to develop autism, when compared to individuals who were not exposed to valproate.

Variable Expressivity of Genes

Thomas Fernandez
Yale Child Study Center, Yale University School of Medicine, New Haven, CT, USA

Definition

It describes the phenomenon of differing clinical features or phenotype among individuals carrying the same gene allele or genotype. Expressivity differs from *penetrance*, which describes the probability that a genetic variation (or allele) will yield the phenotype at all. Variable expression of a phenotype may be influenced by other genetic variations, epigenetic factors, or environment. This term is often used in conjunction with explanations of variable severity of autism-related traits within families. Certain copy number variants (CNVs) associated with autism display variable expressivity, showing association with other neurodevelopmental disorders, including schizophrenia, epilepsy, and intellectual disability.

Indications

According to the official prescribing information, venlafaxine is FDA-approved to treat major depressive disorder (MDD), generalized anxiety disorder (GAD), social anxiety disorder, and panic disorder with or without agoraphobia in adults (Wyeth Pharmaceuticals 2009). It is not approved for children or adolescents under the age of 18 years.

Venlafaxine is not approved for the treatment of autism spectrum disorders (ASDs). ASDs include the DSM-IV-TR diagnoses of autistic disorder, Asperger's disorder, and pervasive developmental disorder, not otherwise specified (PDD-NOS). The decision to use venlafaxine in the treatment of established clinical indications that may co-occur with ASDs, as mentioned above, or for commonly observed symptoms of ASDs, such as hyperactivity, inattention, irritability, aggression, repetitive behaviors, and social impairment, can be made on an individual basis by the treating practitioner. This will be discussed in more detail in the "[Clinical Uses](#)" section.

Mechanisms of Action

Mechanism of Action According to Stahl's *Essential Psychopharmacology* (2008)

Venlafaxine is a serotonin norepinephrine reuptake inhibitor (SNRI), resulting in reuptake blockade of both serotonin and norepinephrine at the level of neuronal synapses and dendrites. This differs from selective serotonin reuptake inhibitors (SSRIs), which block only serotonin reuptake. Usually, the neurotransmitters serotonin and norepinephrine are released from the presynaptic axon terminal to travel across the synaptic cleft and attach to the postsynaptic axon terminal. Any excess neurotransmitter remaining in the cleft is picked up by their respective reuptake transporters in the presynaptic axon to be inactivated for later use or degraded. Serotonin has long been one of the neurotransmitters implicated in the pathophysiology of depression and anxiety disorders. It is hypothesized that a depletion of serotonin available to act on the postsynaptic axon results in symptoms such as depression, nervousness, guilt, loneliness, apathy, and avolition. Antidepressants with serotonin reuptake inhibition, like SSRIs and SNRIs, block serotonin from reuptake at the presynaptic reuptake transporter. This provides excess serotonin to attach to postsynaptic receptors and exerts the intended antidepressant and anxiolytic effects. Additionally, norepinephrine has been found to regulate serotonin release and reuptake. When norepinephrine floods the synaptic cleft, it is taken up by presynaptic alpha-2 receptors, which then decreases the amount of serotonin released at the axon. Norepinephrine can also be taken up by alpha-2 receptors on neuronal dendrites, which sends a signal to the neuron to decrease the amount of serotonin released at the axon terminal. Conversely, norepinephrine that is taken up by dendritic alpha-1 receptors sends a signal to the axon to accelerate serotonin release. This interplay is further complicated by specific serotonin receptors regulating the release of norepinephrine. Furthermore, dopamine is a third neurotransmitter whose regulation is influenced by serotonin and norepinephrine and which likely plays a role in the pathophysiology of depression and anxiety

disorders. When serotonin and norepinephrine reuptake transporters are blocked via SNRIs, dopamine is increased in the prefrontal cortex. This can lead some patients to feel more energized and less fatigued, as well as demonstrate improvements in concentration and attention. The global consequence is that multiple neurotransmitters regulate multiple brain pathways via positive and negative feedback loops. SNRIs capitalize on these complex relationships and are targeted to treat symptoms experienced in mood and anxiety disorders.

Symptoms of depression include depressed mood, apathy, sleep disturbance (typically sleeplessness), both mental and physical fatigue, slowed executive function, psychomotor retardation or agitation, changes in appetite (usually decreased), suicidal thinking, and feelings of guilt or worthlessness. The pathophysiology of these symptoms is thought to result from complicated interactions between serotonin, norepinephrine, and dopamine in various areas of the brain. Depressed mood is thought to stem from hypoactivity of all three neurotransmitters in the amygdala and ventromedial prefrontal cortex. Apathy is hypothesized to be the result of norepinephrine and dopamine dysfunction in the prefrontal cortex, hypothalamus, and nucleus accumbens. Sleep disturbance is linked to all three aforementioned neurotransmitters in the prefrontal cortex, hypothalamus, and basal forebrain. Mental fatigue is thought to be intimately linked to hypoactivity of norepinephrine on noradrenergic receptors in the prefrontal cortex and physical fatigue by hypoactivity of noradrenergic receptors in the descending spinal cord. Dopamine hypoactivity in the prefrontal cortex also contributes to mental fatigue, but dopamine dysfunction is linked to physical fatigue in the striatum, nucleus accumbens, and hypothalamus. Norepinephrine and dopamine dysfunction in the dorsolateral prefrontal cortex is implicated in slowed executive functioning. Psychomotor agitation or retardation is linked to hypoactivity of all three neurotransmitters in the prefrontal cortex, serotonin and dopamine in the striatum and nucleus accumbens, and serotonin and norepinephrine in the cerebellum. Serotonin

hypoactivity in the hypothalamus is implicated in decreased appetite commonly experienced in depression, whereas serotonin hypoactivity in both the ventromedial prefrontal and orbital frontal cortices can result in suicidal ideation. Feelings of guilt or worthlessness are often attributed to serotonin hypoactivity in the ventromedial prefrontal cortex and amygdala.

A number of medications that effectively treat depression also effectively treat anxiety disorders due to an overlap in symptomatology. Anxiety disorders include GAD, obsessive-compulsive disorder (OCD), panic disorder, social anxiety disorder, and posttraumatic stress disorder (PTSD), with core symptoms of all five being anxiety, fear, and worry. Anxiety and fear are due to dysfunction in the amygdala, in part, which synthesizes input from multiple brain areas to determine the need for a fear response. This area is regulated by a number of neurotransmitters, including serotonin and norepinephrine, so these are subsequently implicated in the pathophysiology of anxiety and fear. Both SSRIs and SNRIs increase the amount of serotonin available to the postsynaptic neuron by blocking the serotonin reuptake transporter in the presynaptic neuron and are effective at reducing anxiety and fear in all five anxiety disorders. However, not all SSRIs or SNRIs are approved for the treatment of all five anxiety disorders; prescribers should rely on data demonstrating their efficacy when choosing a treatment. Interestingly, serotonin reuptake transporters have been found to differ genetically from person to person, with certain types leading to differences in how fearful stimuli are processed. This may determine a person's genetic predisposition to anxiety or fear, providing additional information to the prescriber when choosing a treatment. The symptom of worry, on the other hand, is thought to be due to overactivation of a cortico-striatal-thalamic-cortical feedback loop. Like the pathophysiology of anxiety, multiple neurotransmitters are also believed to regulate this loop, including serotonin and norepinephrine. Therefore, certain SSRIs and SNRIs, which manage these neurotransmitters, are often effective at managing worry and obsessional thinking associated with OCD.

Venlafaxine's inhibition of serotonin and norepinephrine reuptake begins immediately, but its antidepressant and anxiolytic effects are often not experienced for up to 6–8 weeks. This is thought to be due to gradual changes on serotonin receptor sensitivity. The belief is that decreased amounts of serotonin hypothesized to occur in depression and anxiety disorders causes the postsynaptic axon to upregulate the number of postsynaptic axonal receptors expressed. In other words, a decreased amount of serotonin in the synaptic cleft results in an increased amount of receptors at the ready. When venlafaxine enters the picture, the level of serotonin in the cleft rises. Postsynaptic receptors sense the serotonin increase and send messages to the axon nucleus about the changes in the synaptic cleft. The nucleus begins downregulating the amount of serotonin receptors ready to receive serotonin. These changes are gradual and are believed to take 6–8 weeks before fully completed, reflecting the amount of time before many patients begin feeling relief from their symptoms.

Venlafaxine's serotonin and norepinephrine reuptake is dose dependent, with the most potent serotonin inhibition occurring at low doses and moderate norepinephrine inhibition occurring at higher doses (Wyeth Pharmaceuticals 2009). In a dosing range of 75–225 mg/day, many patients experience mostly serotonergic blockade effects whereas others experience dual serotonin and norepinephrine blockade effects (Stahl 2009). In a dosing range between 225 and 375 mg/day, most patients experience dual serotonin and norepinephrine blockade effects. Venlafaxine is a substrate for the CYP450 2D6 enzyme. It is metabolized to the major active metabolite O-desmethylvenlafaxine, also known as desvenlafaxine in the liver (Wyeth Pharmaceuticals 2009). O-Desmethylvenlafaxine has higher norepinephrine reuptake inhibition compared to venlafaxine, so administration of the drug results in variable levels of venlafaxine and O-desmethylvenlafaxine in the blood, which can lead to variable norepinephrine inhibition. Given this variability, caution must be taken to appropriately titrate venlafaxine, especially if the patient is taking other medications metabolized by

the CYP450 2D6 enzyme. The advent of desvenlafaxine for the treatment of depression and anxiety disorders, also known by its brand name Pristiq, allows metabolism by CYP450 2D6 to be bypassed.

According to the prescribing information, a single oral dose of venlafaxine had 92% absorption with an absolute bioavailability of 45% (Wyeth Pharmaceuticals 2009). Venlafaxine has been marketed in two forms, Effexor immediate release and Effexor XR (extended release). Effexor XR has a slower rate of absorption but has comparable absorption to the immediate release version, offering the benefit of single daily dosing. Subsequently, Effexor XR is the common form prescribed. Absorption is neither affected by food nor time of day of administration. Given that venlafaxine is metabolized in the liver and excreted by the kidney, dosing adjustments should be made in patients with liver and renal impairment, although there is room for adjustment given patient variability in liver metabolism and renal clearance. In liver impairment, the dose should be decreased by as much as 50% or more. In renal impairment, the dose should be decreased from 25% to 50%, whereas in patients receiving hemodialysis, the dose should be decreased as much as 50%. Venlafaxine has a dose-dependent effect on blood pressure, causing sustained hypertension at 300 mg/day or above, and should therefore be used with caution in patients with hypertension or cardiac conditions (Stahl 2009). Dosing adjustments are not required based on gender or age in adults (Wyeth Pharmaceuticals 2009). Steady-state plasma levels of venlafaxine are achieved no less than 4 days after administration or a dose adjustment.

Clinical Use (Including Side Effects)

FDA-Approved Clinical Uses

According to the official prescribing information, venlafaxine is FDA-approved to treat major depressive disorder (MDD), generalized anxiety disorder (GAD), social anxiety disorder, and panic disorder with or without agoraphobia in adults only (Wyeth Pharmaceuticals 2009). There are currently no FDA-approved uses in children or adolescents. For the treatment of MDD and GAD in adults, Effexor XR is typically started at 75 mg once daily, although some patients may require a starting dose of 37.5 mg/day for 4–7 days before increasing to 75 mg/day. For patients with moderate depression who do not demonstrate improvement in depressive symptoms, Effexor XR can be increased by 75 mg at least every 4 days to a maximum dose of 225 mg/day. In one study examining patients with severe depression, the maximum mean daily dose to achieve symptom control was 350 mg/day, but data exploring the use of Effexor XR above 225 mg/day is limited. According to Stahl, “non-responders at lower doses should try higher doses to be assured the benefits of dual SNRI action,” and up to 600 mg/day has been given (Stahl 2009). Again, there is a possibility for sustained hypertension in doses above 300 mg/day, so prescribers should proceed with caution when considering doses above the recommended dose.

For the treatment of panic disorder in adults, Effexor XR should be started at 37.5 mg/day for 7 days, followed by 75 mg/day for 1 week, and then weekly dosing increases of 75 mg/day to a maximum of 225 mg/day as needed. For the treatment of social anxiety disorder, the daily dose recommendation is 75 mg/day. Switching between Effexor immediate release to Effexor XR can be done with equivalent dosing, although some dosing adjustments may be required based on the clinical response. Effexor immediate release is given in divided daily doses, usually twice or three times daily. It is not clear how long patients should be treated with venlafaxine for maintenance of the aforementioned disorders, so the need for this medication and dosing requirements should be occasionally reassessed. When

discontinuing Effexor XR, the dose should be decreased by 75 mg/day each week, although some patients may require longer taper periods, as long as many months.

According to Stahl, the goal of treatment is complete remission of symptoms and prevention of future relapses, so venlafaxine is taken both throughout and in between clinical relapses (Stahl 2009). Although venlafaxine can eliminate symptoms while being taken, it does not cure depression or anxiety disorders and symptoms can reoccur after the medicine has been stopped. After the first episode of depression in the treatment of adults with MDD, venlafaxine should be taken for 1 year following symptom relief. After the second or any subsequent episodes of depression, treatment with venlafaxine may be indefinite to avoid relapse of symptoms. When treating GAD with venlafaxine, remission for symptoms may be delayed as long as 6 months, requiring adjunctive, short-term treatment of symptom control (Stahl 2008). Once GAD symptoms are controlled, treatment with venlafaxine may be indefinite (Stahl 2009).

Clinical Uses of Venlafaxine in Autism Spectrum Disorders (ASDs)

Researchers have sought various pharmacological treatments to effectively manage symptoms associated with autistic disorder, Asperger’s disorder, and PDD-NOS. Core symptoms include interfering repetitive behaviors, social impairment, and communication impairment, with associated symptoms generally including hyperactivity, inattention, irritability, and aggression. There are currently no randomized, placebo-controlled research studies exploring the use of venlafaxine in treating ASDs, so data supporting its utility in this area is sparse. However, there is one open retrospective clinical report (Hollander et al. 2000) that examined 10 children, adolescents, and young adults (nine males and one female, aged 3–21 years) with the aforementioned ASDs who took venlafaxine for control of core symptoms of ASDs as well as for attention-deficit/hyperactivity disorder (ADHD) symptoms. Using SNRIs for the treatment of symptoms associated with ASDs is based on previous

observations that norepinephrine reuptake inhibitors had been useful in controlling hyperactivity and that some serotonin reuptake inhibitors, like clomipramine, fluoxetine, fluvoxamine, and sertraline, may have some benefit on other symptoms (Cook Jr. et al. 1992; Gordon et al. 1993; McDougale et al. 1996; Steingard et al. 1997). Also, venlafaxine was shown to demonstrate utility in controlling symptoms of ADHD in adults (Findling et al. 1996), which has since been observed in a pediatric population (Findling et al. 2007). The Hollander et al. report used low doses of venlafaxine between 6.25 and 50 mg/day. Six of the ten subjects were considered responders, rated as being “much improved” or “very much improved” on the CGI-I scale. In those patients, all three core dimensions of autism were improved, including repetitive behavior, social relatedness, and communication. Most specifically, the responders demonstrated decreased obsessional thinking, repetitive behaviors, and abnormal vocalizations, as well as improved eye contact, socialization, contextual language use, and complexity of play. Five of the six responders also had improvements in ADHD symptoms. The researchers observed behavioral activation in some patients and warned that this may stem from serotonin reuptake inhibition as evidenced by prior reports (Sanchez et al. 1996). They were reassured that the tendency for venlafaxine to induce clinically significant, dose-dependent hypertension (usually above 300 mg/day) would not affect their subjects as the maximum dose used was 50 mg/day (Thase 1998). This study is limited by the small sample size, the younger ages of the participants, two of the subjects’ concomitant use of other medication, and the retrospective design. Therefore, prescribers should be cautious in generalizing these results to the larger population of patients with ASDs. There have been isolated case reports suggesting the utility of using venlafaxine in the treatment of self-injurious behavior and for ADHD symptoms in patients with ASDs (Carminati et al. 2006), as well as one case report that suggested a concern for increased agitation in a patient with autism and developmental disabilities taking venlafaxine (Marshall et al. 2003). However, there are

currently no randomized, placebo-controlled studies investigating the efficacy of venlafaxine in treating ASDs, so the results of these studies should be regarded with caution before generalizing their utility in treating the greater population of children and adults with ASDs.

Side Effects

Venlafaxine’s side effect profile is a consequence of both serotonin and norepinephrine reuptake blockade on receptors throughout the body (Stahl 2008). Motor activation or tremor can result from acute stimulation by norepinephrine of beta-1 and/or 2 adrenergic receptors in the cerebellum or peripheral sympathetic nervous system. Stimulated cardiac beta-1 receptors can cause changes in heart rate, and changes in blood pressure may result from stimulation of noradrenergic receptors in the brain stem cardiovascular center and descending spinal cord. According to the prescribing information, treatment with Effexor XR above 300 mg/day was associated with sustained hypertension defined as treatment-emergent supine diastolic blood pressure (SDBP) ≥ 90 mmHg and ≥ 10 mmHg above baseline for three consecutive on-therapy visits, although an insufficient number of patients received Effexor XR above 300 mg/day to effectively evaluate this response (Wyeth Pharmaceuticals 2009). Agitation may be experienced from the stimulation of noradrenergic receptors in the amygdala or limbic cortex (Stahl 2008). According to Stahl, there may be “pseudo-anticholinergic” side effects from a reduction of parasympathetic tone, resulting from stimulation of noradrenergic receptors in the sympathetic nervous system (Stahl 2008). In other medications, direct blockade of muscarinic receptors results in classic anticholinergic side effects that include dry mouth, urinary retention, and constipation. SNRIs have no effect on muscarinic receptors, but they do increase sympathetic tone via stimulation of noradrenergic receptors, creating a similar albeit milder effect.

On the other hand, stimulation of serotonin receptor subtypes (5-HT_{2A}, 5-HT_{2C}, 5-HT₃, and 5-HT₄) likely causes other notable side effects. A small amount of increased serotonin shortly

after initiating therapy is often enough to mediate some side effects, even if the clinical benefit is not yet apparent to the patient. Patients who are treated for MDD are at increased risk for experiencing suicidal thinking and behavior. Antidepressants as a class have been shown to increase the risk of suicidal thinking and behavior in children, adolescents, and young adults (ages 18–24) with MDD and other psychiatric disorders (Wyeth Pharmaceuticals 2009). Such risk should be carefully considered when prescribing venlafaxine in the pediatric and young adult population, although venlafaxine is not currently approved for use in populations younger than 18 years. According to Stahl (2009), gastrointestinal side effects can include decreased appetite, nausea, diarrhea, or decreased appetite. Sexual dysfunction can include abnormal ejaculation, abnormal orgasm, or impotence. Central nervous system side effects include rare seizures, headache, nervousness, insomnia, or sedation. Endocrine side effects include syndrome of inappropriate antidiuretic hormone (SIADH) and hyponatremia. Patients with undiagnosed bipolar disorder may be vulnerable to the activating properties of venlafaxine, resulting in hypomania or mania, although this is rare. There has been some reported weight gain in patients taking Effexor, but this is not an expected side effect.

Definition

A ventricle is a chamber or space in the brain which contains cerebrospinal fluid. There are four ventricles in the brain, all of which are contiguous with the central canal of the spinal cord. The ventricles of the brain are the fourth ventricle, the third ventricle, and two lateral ventricles.

Short Description or Definition

Verbal Apraxia (VA) is a speech disorder, or category of speech disorders, in which an individual has difficulty consistently forming and executing motor plans necessary for the articulation and ordering of sounds in words. This difficulty is not due to weakness, slowness, or incoordination of muscles of the mouth and throat, and is frequently attributed to impaired translation of linguistic plans into motor speech patterns. While VA has recently become a topic of interest to providers and families of individuals with communication difficulties, including those with Autism Spectrum Disorders, it has been described and investigated by neurologists, psychologists, and speech pathologists for much longer.

In 1865, Broca first described a similar articulatory language deficit, which he termed aphemia, although this was largely subsumed into the more common term aphasia until the concept of apraxia of speech began to develop in the 1950s and 1960s. The development of VA as a well-defined, discrete entity has been slow, largely because of difficulty establishing whether, indeed, it does resemble other established apraxias (e.g., motor apraxias) wherein automatic function of discrete muscle movements are intact. The problem of assessing discrete elements of speech production outside of speech has dogged efforts to arrive at a standard definition that does not overlap excessively with other disorders.

The concept of a developmental VA was initially proposed by Morley, Court, and Miller in 1954 as a constellation of symptoms similar to those defined in VA in adults that could be used to describe a group of children with speech deficits despite objectively normal development of orofacial and lingual anatomy. The developmental or childhood form of VA becomes manifest during acquisition of language skills, particularly during attempts at complex articulations.

Providers, researchers, and families are interested in determining whether individuals with ASD might have higher rates of DVA, and whether DVA might lead to or exacerbate problems with language development in this group. However, recent evidence suggests that in spite of difficulty with other apraxias, individuals with autism do not show a particularly high rate of DVA, and in fact show speech errors that are easily differentiated from errors shown in children with DVA.

Categorization

Verbal apraxia is variably considered as a discrete entity or disease, a syndrome or symptom cluster, or a category of disorders with more specific subtypes.

It can be classified broadly as developmental, meaning it presents during initial language acquisition, or acquired, meaning it results from later life injury. Within this developmental category, further subdivisions are made on etiological grounds, separating deficits due to known neurological disease from those due to the complex neurobehavioral presentations of genetic or metabolic syndromes, and also from deficits without a known cause, which are referred to as idiopathic.

Just as there is no formal, widely agreed upon definition, there is considerable variety in the terminology and in the classification schemes, and use of particular terms may indicate a provider or researcher's perspective on this controversial diagnosis. For example, the use of "verbal" may indicate emphasis on linguistic deficits over gross or fine motor problems. Likewise, the prefix "dys" often indicates the assumption that the disorder is present from birth, while the prefix "a" often indicates suspicion that the disorder was acquired after birth.

Epidemiology

Incidence of VA is difficult to calculate precisely given the disagreement on its definition and the variety of diagnostic criteria employed. In its

acquired form it is reported in as many as two thirds of patients with aphasia, but rarely reported in isolation. Estimates on the prevalence of the developmental form based on rates of diagnosis in various pediatric clinics indicate population rates between 0.125% and 1.3%. Developmental verbal apraxia (DVA) is more common in children with relatives having communication disorders or learning disabilities. It is diagnosed more frequently in boys, although this could reflect an ascertainment bias if boys are more likely to be referred for speech and language evaluation. Individuals with VA may also have additional apraxia diagnoses, but it is unclear whether these diagnoses are more common in individuals with VA than in individuals without a VA diagnosis.

Natural History, Prognostic Factors, Outcomes

Natural History

Acquired VA most often develops as a consequence of stroke, although it may also be caused by tumors or traumatic brain injuries. It is also described in neurodegenerative diseases, particularly frontotemporal dementias and diseases involving the basal ganglia. It generally occurs with other language deficits (aphasia) or speech deficits (dysarthria).

Children with DVA often present as quiet infants, with parents reporting decreased vocal sounds (e.g., cooing, babbling) compared to unaffected children. It has also been suggested that children with difficulty nursing as infants or "messy eaters" later in development may be exhibiting early signs of VA. Authors who include such children in descriptions of developmental VA report observing a variety of feeding concerns, including frequent choking on food or drink, drooling, or strong food preferences related to oral-motor difficulties. These early symptoms raise the question of whether these children have isolated VA or a concurrent orofacial sensorimotor apraxia.

As they develop, children with DVA tend to acquire and use words and phrases at older ages than their peers. They may develop complex

gestures and non-speech sounds (e.g., grunting) in order to communicate needs with caregivers. Notably, despite their difficulties with productive language, these children often have relatively preserved comprehension of the others’ speech.

Prognostic Factors

Recovery in acquired VA depends on the nature of the causative lesion; fixed insults such as stroke or trauma produce a maximal deficit initially followed by a variable degree of recovery, while expanding lesions such as tumor or degenerative processes often cause progressively worsening symptoms. In addition, prognosis is informed by the age at which the individual acquired the underlying lesion as well as the severity and size of the lesion. Prognostic factors for DVA are less clear, and it is often seen as a disorder that is resistant to treatment. (This may be due to its occasional use as a catch-all diagnosis for those failing to benefit from intervention). However, when progress is seen, it is best accounted for by initial severity of the problem and type and length of services received.

Outcomes

Clinical expression of VA can fluctuate over time, ranging from mild, indicating trouble with only occasional sounds, to severe, in which an individual may not be able to communicate effectively with speech. In acquired apraxia, although

recovery may plateau after 1 year, some improvement may be observed up to 10 years out of an initial insult. While some individuals with DVA may show great improvement with intensive treatment, most individuals will continue to experience symptoms of the disorder throughout the lifetime, although there are scattered, rare reports of complete resolution.

Clinical Expression and Pathophysiology

Verbal apraxia is perhaps more easily recognized than defined, with a characteristic “effortful articulatory groping to produce speech sounds.” Even so, there is great disagreement as to what symptoms characterize DVA, even among practitioners from the same field. The most commonly cited symptoms include difficulty putting together the sounds to form words. In the acquired VA literature, most authors point to a core set of deficits, including highly inconsistent and unpredictable errors (as opposed to the predictable errors of dysarthria due to weakness or spasticity), with primarily phonetic, but also prosodic and non-phonetic features. Many of these same deficits are noted in DVA (Table 1). In acquired VA, reading, writing, and receptive language deficits should be absent, although this distinction may be less clear in individuals with DVA who have yet to acquire written language. Some authors note oral-

Verbal Apraxia, Table 1 Features of verbal apraxia

General symptom	Specific symptom	Example
Difficulty forming sounds	Groping	Unnecessary movements of the lips, tongue, or jaw prior to speaking
	Difficulty with “voiced” consonants	Saying “cap” instead of “cab,” “pat” instead of “pad”
	Leaving out sounds	“Unbelievable” becomes “unbeevable”
	Adding sounds	“Eraser” becomes “eraseler”
	Reversing sounds	Saying “miskate” instead of “mistake”
Difficulty increases with complexity	Difficulty repeating a word	Repeat “buttercup” yields “buttercup, puddercut, buttergup”
	Disappearance of words	Loss of a previously mastered word
	Different day-to-day performance	Severity varies day to day
Odd speech characteristics	Incorrect use of prosody	Using an “angry voice” when feeling happy
	Nasal tone	Child sounds as if they are “talking through the nose”

lingual apraxia (difficulty with complex oral or tongue non-speech movements with intact component movements) should be absent, and still others expand the definition to include those with oral sensory deficits.

Localization of verbal apraxia is difficult, with most authors suggesting problems in the dominant frontal lobe, specifically the inferior frontal gyrus (i.e., Broca's area), which is commonly implicated in the eponymous aphasia. Other regions that have been investigated include the insular cortex, ill-defined subcortical regions, and the parietal lobe. Lesions in these regions are implicated in non-verbal apraxias, and are thought to interrupt connections between motor centers and storage of learned motor engrams. The fundamental problem in VA, as envisioned by Darley and others, is a disruption of the "motor speech programmer," wherein received abstract linguistic plans cannot be translated into the specific sequence of motor movements required for speech. There is no evidence that children with DVA show specific brain lesions or differences in brain structure. However, the concept of a disconnection between linguistic processing and motor planning has been proposed, and multiple specific neuro-linguistic processes implicated, including oral-motor programming, pre-articulatory sequencing, auditory processing, perceptual abilities and their link to memory, the process of selecting and retrieving required sounds, and many others. There is some evidence that DVA is heritable. However, it is difficult to study the genetics of the disorder given disagreement regarding diagnostic criteria.

Clinical expression of DVA in children with ASDs can be difficult to disentangle from general language delay. In addition, children with ASDs, like children with DVA, frequently show difficulty with prosody production. However, speech errors in DVA are marked by their inconsistency (e.g., making different errors from day to day), while they may be more persistent in the speech of an individual with an ASD.

Evaluation and Differential Diagnosis

Evaluation for apraxia of speech is most often undertaken by speech pathologists, who utilize a

variety of skills, checklists, and testing instruments to form their conclusions. As there is no single diagnostic test, repeated visits over time are used to determine if the diagnosis is a good fit. One test used to diagnose DVA is the Motor Speech Evaluation (MSE), which includes assessment of vowel prolongation, sequential and alternating diadochokinesis (e.g., speeded repetition of phonemes), as well as repetition of words of increasing syllable length (e.g., *jab jabber, jabberin*), repetition of sentences, and reading aloud.

Other tools are often used to rule out differential possibilities like aphasia or dysarthria, including the Frenchay test for dysarthria and the Boston Diagnostic Aphasia Exam. In addition, the clinician must exclude developmental delay of speech, in which speech development is slow but otherwise typical. Other common comorbidities include poor vocabulary, incorrect grammar, difficulty in clearly organizing spoken information, problems with reading, writing, spelling, or math, coordination or motor skill problems, and chewing and swallowing difficulties. In individuals where concerns primarily relate to written speech, dyslexia may better account for symptoms.

In addition to the above assessments, many clinicians rely on checklists from seminal papers in the field, and when diagnosing acquired VA, speech pathologists appear to have good intra- and interrater reliability. Most studies suggest that this is not the case for DVA. In a study of 75 Speech Language Pathologists asked to name the most essential symptoms for diagnosis of DVA, 50 different symptoms were named, and none were listed by more than half of all respondents. Despite this variability, a diagnosis of DVA can be generally given if a child's symptoms fit some or all of the descriptive criteria in Table 1, and if the difficulties do not result from paralysis or weakness of the muscles involved in speech.

While children with ASDs and children with DVA both show speech deficits, differential diagnosis can be made based on symptoms specific to each disorder. Child with ASDs will also show marked difficulty or awkwardness during social interactions along with odd or stereotyped behaviors or interests, while these symptoms are not

noted in children with DVA. Children with DVA can be distinguished generally by the presence of inconsistent errors, intact receptive language skills, and typical nonverbal social interactions.

Treatment

There are currently no pharmacological or medical treatments for Developmental or Acquired Verbal Apraxia. Speech therapists instead utilize a variety of neuropsychological and rehabilitative approaches. No one approach has been shown to be most effective, but improvement in symptoms usually requires intensive 1:1 therapy. The most common approaches used to treat both types of VA are focused on linguistic goals, motor-programming goals, or a combination thereof. Therapists focused on linguistics will help the child learn sounds and rules about sounds and sound sequences. This is more commonly utilized with preschoolers and very young elementary-aged children. Other providers focus on motor-programming skills. These involve teaching the child to make sounds and sequences of sounds through repetition. Many therapists use both of methods in treatment. Additional methods include using specific sensory and gestural cuing to facilitate fluent speech. For children with a more severe form of DVA, a therapist might recommend the use of additional communication methods, including sign language, picture or communication notebooks, or an electronic communication device. Finally, the above treatments may be paired with physical therapy, especially for children who have nonverbal motoric deficits. For children and adults with other communication disorders, including ASDs, these goals can be incorporated into speech-language therapy along with goals specific to the comorbid disorder.

well. Verbal Auditory Agnosia is a language disorder due to brain dysfunction, similar to aphasia.

Categorization

Individuals with Verbal Auditory Agnosia are unable to recognize that acoustic streams of complex sounds (containing periodic energy) spoken by humans (i.e., the fundamental frequency of the vocal cord vibration) can convey meaning, despite normal auditory sensitivity. As shown in Table 1, they can detect the presence of sound and detect changes in sound whether the changes are verbal or nonverbal. The difficulty occurs at the next level of processing, where individuals are unable to recognize speech as linguistic information, yet they can recognize and name nonverbal sounds (e.g., a dog barking). The next level of auditory processing, comprehension, is also affected for linguistic information such that they have difficulty answering simple questions. However, individuals with Verbal Auditory Agnosia could appropriately associate a siren sound with a plausible scenario in which it might occur, outside of a jail.

Short Description or Definition

Verbal Auditory Agnosia is the inability to recognize linguistic stimuli presented verbally, despite normal hearing and intelligence. In most cases, it is acquired via brain injury, but can be congenital as

Epidemiology

Verbal Auditory Agnosia is considered rare and therefore there are no reports on the prevalence or incidence of this condition. The International Statistical Classification of Diseases and Related Health Problems (ICD-9) only includes a reference to “agnosia” under the code 784.69 “Other,” which also includes acalculia, agraphia, and apraxia. The 784.69 is a subcategory under 784.6 “Other Symbolic Dysfunction.” In the new classification available in 2013 (ICD-10), there will be a code for agnosia, R481, but it will not be specific to verbal auditory agnosia. Of the limited reports in the literature which refer to a complex of symptoms which may include auditory agnosia, only five authors provide information regarding the demographics of individual cases who specifically present Verbal Auditory Agnosia. Of these, there were reports of three

females, ages 7, 19, and 40 years, and two males, ages 7 and 51 years. The onset varied and was suggestive of being an acquired condition such as stroke (two cases) or secondary to a congenital condition such as a syndrome or developmental disorder (three cases).

Natural History, Prognostic Factors, Outcomes

The earliest report of someone with Verbal Auditory Agnosia was in 1930. It is considered a rare condition that someone with normal hearing would have such difficulty with recognition of words, yet be capable of recognizing environmental sounds. The prognosis is generally better than that for someone with Wernicke's aphasia, which

also affects the temporal lobe, because individuals with Verbal Auditory Agnosia still have relatively good spoken language skills. Furthermore, the receptive difficulty is limited to the auditory domain so that other domains such as vision, which may be stronger, may be used to facilitate communication and learning through written language. Depending upon the age of onset if caused by a cerebral insult, it can impact the degree to which the production of speech is affected. For example, if the Verbal Auditory Agnosia occurs during the early years of acquiring speech, the acoustic patterns or templates, upon which the individual's own speech is compared, may not develop. Hence, the auditory/motor coordination for speech production is impaired. In contrast, if the Verbal Auditory Agnosia onset occurs after the development of fully intelligible speech, the

general prognosis remains high because more compensatory strategies may be developed based on the strength of the production skills.

Clinical Expression and Pathophysiology

While the cause of Verbal Auditory Agnosia is unknown, research shows that those with the condition have sustained damage to the left temporal lobe. This region of the brain contains Wernicke's area, where speech is processed and meaning is derived from the spoken word. Receptive language deficits can almost always be linked to an infarct or abnormality in Wernicke's area.

Individuals with Verbal Auditory Agnosia are unable to recognize that acoustic streams of complex sounds containing periodic energy, (i.e., the fundamental frequency of the vocal cord vibration) can convey meaning despite normal auditory sensitivity. This disorder may be associated with Landau-Kleffner syndrome, in which an individual also suffers from convulsions and seizures. These individuals may gradually lose their ability to speak along with their impaired ability to discriminate speech sounds spoken by others.

Evaluation and Differential Diagnosis

An appropriate evaluation for Verbal Auditory Agnosia includes four steps: (a) evaluate sound awareness (b) evaluate sound discrimination (c) evaluate auditory identification/recognition (d) evaluate auditory comprehension.

The first step in the evaluation process is to determine that hearing sensitivity is within normal limits. If a standard audiometric evaluation cannot be completed, electrophysiological techniques, such as measurement of electrical responses to sound at the brainstem, Auditory Brainstem Response (ABR), should be used. Hearing sensitivity tests are aimed at evaluation at the simplest level of processing, awareness, and are known as speech awareness or detection thresholds. A response may range from eye widening in an infant to raising one's hand to indicate detection. Although auditory discrimination, the next level

of auditory processing, can be evaluated in many ways, there are no tests of discrimination routinely used in the audiological battery. The evaluation of discrimination, or one's ability to detect a change in the acoustic stimulus, is accomplished in young infants by using a dishabituation response recorded as a change in sucking or heart rate. In toddlers, the dishabituation response may be a head turn. When paired with appropriate visual training, children's speech discrimination may be tested with the oddity paradigm as young as 4 years of age. In the oddity paradigm, three stimuli are presented, two of which are acoustically identical. The child's task is to identify which of the three stimuli was different. By age 5 or 6, a same/different paradigm is often used to evaluate discrimination. For adults, discrimination of speech features has most often been measured using an ABX procedure in which the listener determines if the first (A) or second (B) stimulus is the same as the last one (X). In all of these procedures, the patient is required to respond only when a change has been perceived in some acoustic dimension of the stimulus, such as the intensity, frequency, or timing. Therefore, when assessing auditory discrimination, the patient is merely comparing stimuli. One commercially available tests of discrimination include the Goldman-Fristoe-Woodcock Test of Auditory Discrimination (1970), which has norms for ages 3:8 to 70+ years.

The next level, auditory identification/recognition, may be evaluated by asking the listener to choose an object, point to a picture, or produce the stimulus in written or verbal form. Individuals must recognize the sequence of sounds and then associate it with some previous experience. Recognition tasks differ from the next level of processing in that no semantic processing is required. That is, the patient may be able to imitate the word "book" but not be able to define it or use it in a sentence. Typical audiological speech assessments at the recognition level of processing include the speech recognition threshold and the word/sentence recognition score. It is important to note that audiologists typically perform recognition tests as a function of intensity level. A recognition test is usually administered at the threshold level and at

one or more supra-threshold levels. It is becoming increasingly common to also include another recognition test at a supra-threshold level in the presence of background noise.

Auditory comprehension, the final level of auditory processing, is not routinely assessed during the clinical audiological battery. Following simple commands or answering “wh-” questions at a fixed intensity level in a sound booth removes the possibility of errors resulting from distractions or intensity variations with live-voice presentation.

In addition to the audiological battery, age-appropriate language tests may be used. The individual with VAA will have difficulty with any task that requires identification and/or comprehension of verbal stimuli. There is currently no one test that will allow assessment of identification of nonspeech sounds in the environment such as horns, animals, or music in contrast to the identification and comprehension of words and/or phrases. The ability to identify nonspeech sounds combined with an inability to identify words/phrases are the classic symptoms of one with Verbal Auditory Agnosia.

Treatment

There has been limited research on the treatment methods for Verbal Auditory Agnosia because there have been so few cases reported. Most of the literature has been focused on the differential diagnosis of these individuals using techniques such as cortical event-related potentials, auditory brainstem responses, magnetic resonance imaging, SPECT imaging, and cranial computed tomography. Treatment methods vary for Verbal Auditory Agnosia based on individual severity. Strategies used to treat auditory processing disorder (APD) might also be effective because they are designed to strengthen processing via the auditory channel. Individuals with this diagnosis present with a delay in cortical components, suggesting they need more time to process speech. Therapy strategies include:

- Giving frequent breaks in listening time
- Limiting background noises in the environment

- Providing more pauses in speech stimuli to accommodate slower processing speeds
- Computer-based auditory training exercises
- Assistive listening devices such as FM systems

There are no standard psychopharmacological treatments for VAA; however, there has been one report of using diazepam with one individual who presented symptoms of VAA (Nagafuchi et al. 1993). The 7-year-old participant with VAA was injected with 10 mg of diazepam, which was followed by a daily dose of 2 mg for 2 years. The individual with VAA returned to within normal limits on auditory discrimination tasks involving monosyllabic words. This study has not been replicated, so its effect on all individuals with VAA is unknown.

Another approach is to capitalize on one's strengths in other areas of functioning to increase verbal processing. For example, if an individual with VAA is a strong reader, communication strategies that involve the printed words would be effective. A progressive approach of pairing the auditory label with the printed word to convey meaning may be tried to bridge associations between the linguistic concepts that may ultimately transfer to the auditory domain. Computerized auditory training programs also may be used to increase independent efforts to improve auditory processing.

Definition

Verbal Behavior, Verbal Behavior intervention, or Applied Verbal Behavior (AVB) is an application of Applied Behavior Analysis (ABA) therapy that incorporates B. F. Skinner’s 1957 functional analysis of the acquisition of language in individuals. Skinner’s book only describes verbal behavior and does not specifically describe how to apply verbal behavior in an intervention setting. The primary focus in Verbal Behavior intervention is to identify deficits in an individual’s functional language and skills to determine how to best capture a child’s motivation. This motivation helps to pair the value of a word and the word itself; this is done through behavior training. Verbal Behavior intervention used with individuals diagnosed with Autism Spectrum Disorders (ASD) often works on mastering four distinct components of Skinner’s verbal behavior (i.e., mands, tacts, echoics, and intraverbals). Additional verbal intervention can be completed on receptive skills (in the areas of

function, feature, classification), textual, written (dictation), and imitation.

Historical Background

In 1957, Skinner wrote *Verbal Behavior*. In his book, Skinner argued that communication is a form of behavior that follows the same principles as other forms of behavior. Furthermore, Skinner stated that verbal behavior is subject to the same controlling variables as all other voluntary behavior. However, verbal behavior is indirect and mediated by the behavior of other people and nonverbal behavior is direct and mediated by the environment. Because of this specific distinction, Skinner believed that verbal behavior required a separate functional analysis.

Since the introduction of Skinner's theory of verbal behavior in Applied Behavior Analysis (ABA) therapy with individuals with ASD, the incorporation of this form of intervention has grown in its popularity as successful behavioral programs for individuals with ASD possess verbal behavior targets (i.e., communication) as well as social behavior targets, motor targets, and self-help targets. Skinner's original theory has not changed, but the implementation of Verbal Behavior intervention continues to progress as more is learned about how children, both with and without ASD, develop language.

Rationale or Underlying Theory

According to Skinner, verbal behavior can be grouped into four distinct units or operants as he identified them. The four operants are: (1) mands, (2) tacts, (3) echoics, and (4) intraverbals. Each operant serves a different and specific function in the acquisition of verbal behavior and have been incorporated into Verbal Behavior intervention for individuals with an ASD diagnosis.

Mands are verbal requests for something that an individual desires or wants. It is believed that if individuals with an ASD diagnosis do not learn mands, they are not able to control their environment and social settings. It is theorized that

learning mands makes the acquisition of echoics and tacts easier for the individual. An example of a mand is when a child is learning to say the word "cookie" for requesting a cookie. The word itself is reinforced when the child is given the cookie after successfully saying the word "cookie" and, according to Skinner's verbal behavior theory, the child will use the word "cookie" again when the same context is presented to the child.

Tact is the ability to label an object. Tacts are elicited by the use of a specific object. For example, if a child sees a picture of a dog and says the word "dog," the child is labeling the item (i.e., the picture) with a specific word (i.e., the word "dog"). A pure tact is when labeling occurs naturally whereas an impure tact is when labeling occurs through manipulation.

Echoic is the ability to imitate natural sounds. Echoic builds on the principle that most people learn by imitation. Reinforcement of echoic responses will increase the likelihood of future echoic responses to occur in an individual without prompting. In Verbal Behavior intervention, echoics include vocal imitation as well as sign language. It is believed that if a child is able to echo the word, the child will be motivated to use the same word again in the future in order to obtain the same object.

Intraverbal is a prerequisite for more advanced verbal skills like conversation or social language. It is responding to another individual's verbal response and can be motivated by social reinforcement. Intraverbals can be simple conversation, categorizations, or verbal responses to another person's verbal behavior; they are an essential goal of Verbal Behavior intervention. Intraverbal responses to the language of another person are usually in response to "Wh-" question (i.e., "Who?" "What?" "Where?" "When?" "Why?"). An example of an intraverbal is if a parent asks a child, "Where do you go swimming?" and the child responds, "Pool." An example of an intraverbal fill-in is if a parent asks a child, "You go swimming in the . . ." and the child completes the sentence "Pool." Intraverbals allow individuals to discuss stimuli that are not present and without the presence of a visual cue prompt.

Verbal Behavior intervention teaches mands, tacts, echoics, and intraverbals in such a manner that there is very specific and systematic reinforcement for each specific verbal response. In Skinner's functional analysis of language, he proposed that language is a behavior that is caused by environmental variables such as reinforcement, motivation, extinction, and punishment. When intervention systematically manipulates these variables, therapists are able to increase motivation for a client to engage in a targeted verbal response (vocal or nonvocal).

Goals and Objectives

The primary goal of Verbal Behavior intervention is to promote language development in any individual with language deficits. Verbal Behavior intervention aims to capture the motivation of an individual to pair the value and function of a word and the word itself. The understanding, acquisition, and production of verbal behavior from the targeted individual means vocal behavior, but also includes sign language and the use of augmented speaking devices. Sign language and augmented speaking devices are extremely helpful while teaching mands, tacts, and even intraverbals. Through a behavioral therapist, the individual learns the relationship between language use and requests to obtain desired items or activities.

Some examples of objectives from a Verbal Behavior intervention session are to increase the frequency of independent requests for toileting (i.e., mand for "toilet") and to increase the frequency of independent requests for a break during a session, help during a session, or stop the session. These mands are important for communication because they provide immediate access to toileting or to a break. Additionally, these mands are positive replacement behaviors because the use of them will produce immediate access to toileting when needed or a break from a non-preferred activity. Another example of an individual's Verbal Behavior intervention session would be the use of mands for information. Once the mands for that individual are successful

for basic needs and in high establishing operations/motivating operations (or EO/MO) situations, the therapist may then work to create situations where requests for information help the individual gain access to more motivating items. For example, if a child wants to color but needs crayons, the therapist will teach the mand for crayons or the location of crayons when crayons are not present.

Treatment Participants

Verbal Behavior intervention is used with children who have deficits in language and may be applied to individuals with or without ASD. Although it may be effective in teaching some communication skills to children with ASD, additional research is still needed to determine if the procedures in Verbal Behavior interventions are effective for teaching complex, flexible, and generalized verbal skills for individuals with ASD.

Mands need to be taught first for children diagnosed with ASD. Individuals are then taught tacts and the different function between a mand and a tact. That is, individuals must understand the difference between requesting desired objects (mand) and labeling objects (tact). After these concepts are learned, individuals with ASD are then taught intraverbals. This is perhaps the most important verbal behavior component of the intervention as individuals learn to answer various "Wh-" questions. Echoics are also an important part of the intervention for individuals diagnosed with ASD. Echoic learning in the natural environment is critical to the generalization of learned skills and imitation and implementation of social language in the natural environment.

All individuals diagnosed with ASD with a language deficit can benefit from Verbal Behavior intervention. Verbal Behavior intervention provides continual reinforcement and opportunities to continue increasing the fluency of mands, tacts, echoics, and intraverbals. Additionally, the skills that are being taught in Verbal Behavior intervention are key components of social and communication behavior.

Treatment Procedures

The structure of Verbal Behavior intervention is based on the format of ABA therapy, with a therapist working directly with a child in a structured setting with predetermined individualized goals. Verbal Behavior intervention is designed to motivate a child to learn language by finding a pairing between a word and the value of the word. Verbal Behavior intervention also emphasizes the function of words and language instead of the form. In Verbal Behavior intervention, more importance is placed on mands than tacts stemming from the belief that the use of language is more important than just the knowledge of language.

The format of a discrete trial is in the order of stimulus-response-consequence. Sessions contain a combination of verbal operants with the opportunity of the mand. Verbal request for a desired item or activity is the targeted response. Mands are first taught to the individual. The intervention should be structured in a formal training session and in the child's natural environment so that verbal and social interactions may be generalized and practiced with peers, parents, and others outside of the formal therapy environment. The therapist should make the intervention as fun as possible for the child. This is done by using frequent mand trials, varying the pace of the sessions, the tone of voice of the therapist, using errorless learning procedures instead of using the word "no," and minimizing the use of punishments. Verbal Behavior intervention generally involves 30 or more h per week of scheduled therapy. Families are highly encouraged to use the skills learned in the structured sessions in their daily lives.

Verbal Behavior intervention uses reinforcers at the beginning of therapy with an individual, and eventually fades them out of the therapy to a more natural reinforcement schedule. However, fading is not done with mands as the reinforcer for the targeted behavior is not praise but the requested item. Reinforcers are functionally related to the type of response the child is producing. Reinforcers, such as food and toys, are then faded to natural reinforcers that maintain the specific type of response elicited from the child.

Efficacy Information

To date, research studies on the efficacy of the use of Verbal Behavior intervention to increase vocalizations in nonverbal children are inconclusive. Inconclusive empirically supported research findings on the efficacy of Verbal Behavior intervention stem from several issues. First, it is challenging for a research study to appropriately separate the exact component of Verbal Behavior intervention that contributes to the verbal gains seen in the participants (Bondy et al. 2010). Second, a majority of the research looking at the potential benefits of Verbal Behavior intervention in individuals, with and without language deficits, focus on interventions targeting a single operant (Carr and Firth 2005), thus making findings not applicable to Verbal Behavior intervention as a whole. The lack of outcome studies, especially in the ASD literature, continues to contribute to the lack of evidence-based support for Verbal Behavior intervention and is primarily due to the complexities of measuring and replicating intervention studies. However, research findings do exist on the independent benefits of mands, tacts, and intraverbals (Sautter and LeBlanc 2006). Each operant has been proven to provide verbal gains in individuals with language deficits, both with and without ASD.

Further research is needed to determine whether the approaches used in Verbal Behavior intervention are in fact unique to ABA therapy or if they are simply another way to label tools and skills already used in conventional ABA therapy. Additional research is also needed to test the overall effectiveness of the use of curricula based on Skinner's analysis of verbal behavior as well as outcome studies with larger sample sizes.

Outcome Measurement

The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP) is a criterion-referenced assessment tool, curriculum guide, and skills tracking system that is designed for children with ASD and other individuals who

demonstrate language deficits. The VB-MAPP is comprised of five components that collectively provide: (a) a baseline level of performance (the VB-MAPP Milestones Assessment), (b) a direction for intervention (the VB-MAPP Barrier Assessment), (c) a system for tracking skills acquisition (the VB-MAPP Transition Assessment), (d) a framework for curriculum development (the VB-MAPP Task Analysis and Skills Tracking), and (e) a guide for placement recommendations (the VB-MAPP Placement and IEP Goals).

Qualifications of Treatment Providers

Verbal Behavior intervention is conducted by Board Certified Behavioral Analysts (BCBA), psychologists, speech therapists, special education teachers, and other professionals who have been trained in ABA therapy and BCBA certified. Professionals who are not BCBA certified, such as Board Certified Assistant Behavioral Analysts (BCaBA), may conduct Verbal Behavior intervention under the direct supervision of a certified BCBA.

To apply for BCBA certification, an individual must have at least a Masters level degree in a human service field, such as Behavior Analysis, psychology, or special education. Individuals must also have completed coursework in behavior analysis that cover ethical considerations, behavioral assessment, experimental evaluation of interventions, measuring and interpreting behavioral data, and behavioral change procedures. An individual must also have obtained supervised training from a certified BCBA. An application needs to be completed and approved. The individual must also take and pass a standardized examination. An individual may also obtain BCBA certification if he/she has at least 1 year faculty appointment at a university or college where he/she must have (1) taught a class on the principles of behavior, single-subject research methods, applications of basic principles of behavior in applied settings, and ethical issues and (2) conducted and published research on behavior analysis. An individual may also apply for BCBA certification if he/she has a doctoral degree for at

least 10 years in behavior analysis, psychology, education, or another related field approved by the Behavioral Analyst Certification Board (BACB).

To obtain BCBA certification, an individual must then pass a standardized exam. The BCBA exam consists of 150 multiple-choice questions and the BCaBA exam consists of 132 multiple-choice questions. Both exams cover 10 content areas: (1) ethical considerations; (2) definition and characteristics; (3) principles, processes, and concepts; (4) behavioral assessment; (5) experimental evaluation of interventions; (6) measurement of behavior; (7) displaying and interpreting behavioral data; (8) selecting intervention outcomes and strategies; (9) behavior change procedures; and (10) systems support. Examiners are given 4 h to complete the exam. The exams are administered on computers and are offered three times a year in 1-month testing windows.

Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP)

Description

The Verbal Behavior Milestones Assessment and Placement Program (VB-MAPP), developed by Mark L. Sundberg, Ph.D., BCBA-D, is a criterion-referenced assessment that provides individualized information regarding a learner's current level of responding across a variety of verbal and learning behavior skills that typically emerge by age 48 months. Within the VB-MAPP is the Early Echoic Skills Assessment (EESA) subtest, developed by Barbara E. Esch, Ph.D., BCBA-D, CCC-SLP, which is used in combination with the VB-MAPP. The information gained through the completion of the VB-MAPP may be used to drive academic and behavioral programming including the development of goals and objectives (Sundberg 2014).

The *VB-MAPP Protocol*. The *VB-MAPP Protocol* is the testing booklet used for administration of the assessment. One protocol booklet should be used per learner, and each protocol booklet may be used for up to four administrations of the VB-MAPP. The *VB-MAPP Protocol* contains the VB-MAPP Milestones Assessment, Early Echoic Skills Assessment (ESSA), VB-MAPP Barriers Assessment, VB-MAPP Transition Assessment, and a Skills Tracking Chart for the VB-MAPP Task Analysis and Supporting Skills section (Sundberg 2008).

Milestones Assessment. The Milestones Assessment determines the baseline levels for

170 skills across 16 developmental domains: mand; tact; listener behavior; visual perceptual/match-to-sample (VP/MTS); play; social; imitation; echoic skills; vocal behavior; listener responding by feature, function, and class (LRFFC); intraverbals; group; linguistics; reading; writing; and math (Sundberg 2008). The domains are grouped into three levels based upon typical skills observed for a learner within the specified developmental age range (Level 1: 0–18 months, Level 2: 18–30 months, and Level 3: 30–48 months). The age ranges are available to easily group the skills into developmental ranges and should not be used to provide a developmental age-equivalency score. The Milestones Assessment involves either direct testing, observation, either testing or observation, or timed observation of the assessed skill. The assessment method for each individual skill is stated on the scoring page next to each individual skill, and a comments/notes section is provided below the skill domain area. Each individual skill receives a score of 0 (did not demonstrate skill), 1/2 (partially demonstrated skill), or 1 (demonstrated skill). The score is placed in the grid to the left of the skill description labelled 1st, 2nd, 3rd, and 4th, which represents the current testing administration number. The sum of all five skills per domain is transferred to the corresponding testing administration grid located above the skill domain area. Within the Milestones Assessment is the EESA subtest. The EESA assesses as learner's echoic skills (i.e., vocal imitation) across five separate groups including simple and reduplicated syllables, two-syllable combinations, three-syllable combinations, prosody within spoken phrases (e.g., emphasize syllables), and prosody across other contexts (e.g., pitch, volume, and duration; Sundberg 2008).

Barriers Assessment. The Barriers Assessment determines the learner's baseline levels across 24 areas that commonly contribute to decreased language development and reduced learning rates (Sundberg 2008). Examples of common barriers include prompt dependency, failure to generalize, reinforcement dependency, and obsessive-compulsive behavior. Each barrier is scored on a 0–4 Likert scale ranging from 0 to 4; a low score

indicates that the assessed barrier does not impact the learner, and a high score indicates a severe barrier for the learner (Sundberg 2008).

Transition Assessment. The Transition Assessment determines the effectiveness of the learners current programming and whether the learner has the prerequisite skills needed to learn in a more naturalistic arrangement (Sundberg 2014). The Transition Assessment provides information that may lead to a better understanding of the appropriate learning format and educational setting for the learner. Similar to the Barriers Assessment, each skill has an associated grid to document the score. Scores in the Transition Assessment range from 1 to 5; a low score indicates a more intensive and individualized instructional setting which may be more appropriate for the learner, and a high score indicates that the learner may learn most effectively in a more naturalistic educational environment. The transition skills are grouped into three larger categories: VB-MAPP Scores and Academic Independence, Learning Patterns, and Self-Help, Spontaneity, and Self-Direction. Examples of assessed skills include *works independently on academic tasks*, *retention of new skills*, and *adaptability to change* (Sundberg 2008).

Task Analysis and Supporting Skills Tracking Guide. The Task Analysis and Supporting Skills Tracking Guide component included with the *VB-MAPP Protocol* includes identified prerequisite and supporting skills to encourage further development for milestone skills across the Milestones Assessment (Sundberg 2014). Each milestone skill is listed with suggested prerequisite and supporting skills. Supporting skills are indicated with an asterisk, whereas prerequisite skills do not have a symbol. An example of a prerequisite skill is that the learner should “put 2 similar items together 2 times” prior to demonstrating the milestone skill of “matches any 10 identical items” (Sundberg 2008, pp. 41). An example of a supporting skill is that the learner “completes a 3-piece inset puzzle without physical prompts” (Sundberg 2008, pp. 41). When a prerequisite or supporting skill meets mastery, the testing administrator should indicate that the objective is met by placing a mark in the corresponding box. Items

that indicate a prerequisite or supporting skill met mastery should be transferred to the Skills Tracking Chart which provides the assessor with a visual reference of the learner's progress (Sundberg 2008).

The VB-MAPP Guide. The *VB-MAPP Guide* is the user manual for the VB-MAPP assessment. It provides background information on the overall assessment; a brief introduction to B. F. Skinner's *Verbal Behavior* (1957); assessment tool administration guidelines; scoring instructions for the Milestones, Barriers, and Transition Assessments; and a guide for program development including suggested goals and objectives for Individualized Educational Plans (Sundberg 2014). An introductory review of verbal behavior is provided in the *VB-MAPP Guide* to orient the administrator to the necessary concepts of verbal behavior that are required to complete the assessment. The administration guidelines describe general strategies to increase the effectiveness of the assessment process. The scoring instructions provide additional information regarding the skill being assessed such as appropriate sample materials, an example of how to present the skill, and specific criteria for scoring. Suggested learning objectives are separated into levels that correspond to the levels on the Milestones Assessment (Sundberg 2014).

Historical Background

The VB-MAPP is based on Skinner's *Verbal Behavior* (1957). Skinner used the term *verbal behavior* intentionally to differentiate his theory from more traditional theories of speech and language development. He wrote that the term *speech* was too limiting in that it excluded other types of communication such as sign language, exchanges via pictures, and writing. He also proposed that the word *language* was too broad as it encompassed entire languages (e.g., English). Traditional theories of language are broken primarily into three categories: receptive language, expressive language, and pragmatic language. However, Skinner identified several specific components of verbal behavior, referred to as verbal operants. Skinner categorized verbal behavior

into two main categories – the behavior of the speaker and that of the listener (1957). The VB-MAPP assesses speaker behavior across several verbal operants including mands, tacts, intraverbals, echoics, motor imitation as related to sign language, textual, copying a text, and transcription. The VB-MAPP also assesses for listener skills such as following instructions (Sundberg 2008).

Psychometric Data

The VB-MAPP is a criterion-referenced assessment (Sundberg 2014). Criterion-referenced assessments are designed to provide information regarding a learner's performance on specific testing items over the course of time in order to identify progress (Powers et al. 2014). Although the VB-MAPP provides age ranges for each milestone skill level, the assessment is not designed to provide a standardized score, and therefore a limitation of this assessment tool includes the inability to compare the learner's scores to their same-aged peer group.

The Milestones Assessment. The Milestones Assessment Scoring Form is a color-coded visual grid that represents each of the three skill levels. Each level contains columns with a maximum score of 5 for each of the relevant developmental domains assessed in that level. Each individual milestone score is transferred to the Milestones Assessment Scoring Form and represented on the visual grid as either a blank (0), partially filled (1/2), or fully filled (1) scoring box. The total sum of each skill domain area across all three levels is then combined to determine the total assessment score which has a maximum score of 170. Progress is demonstrated and tracked on the Scoring Form for up to four testing administrations.

The EESA. The EESA is initially scored separate from the Milestones Assessment; however, the EESA score is then incorporated into the Milestones Assessment Scoring. There are 100 possible points on the EESA. Points are assigned based on the production of correct sounds. Each item may be scored as (1) point for all correct sounds; (1/2) point for recognizable

approximations with the correct vowel sounds, addition of syllables, and/or addition of consonant sounds; or (0) points for no response, unrecognizable approximations, omitted syllables, and/or incorrect vowel usage (Sundberg 2014).

The Barriers Assessment. The scores from the VB-MAPP Barriers Assessment should be transferred to the corresponding Scoring Form. The Barriers Assessment includes a Likert scale (0–4) in which assessor scores the child on 24 potential barriers to learning. A score of 0 on the Likert scale indicates the barrier is not a concern, while a score of 4 indicates the barrier is of significant concern. A scores of 2, 3, or 4 warrant additional intervention to prevent the barrier from becoming worse (Sundberg 2014). There is a possible total of 96 points on the VB-MAPP Barriers Assessment. Similar to the Milestones Assessment, each area has an individual grid to write the score for the current testing administration. Individual scores are transferred to the Scoring Form which is comprised of 24 individual smaller grids, separated by each barrier area, and can document scoring information for four testing administrations (Sundberg 2008).

The Transition Assessment. The scores from the VB-MAPP Transition Assessment should be represented on the Transition Assessment Scoring Form. The Transition Assessment provides a Likert scale (1–5) with scores ranging between 4 and 5 indicating that the child may benefit from opportunities in a mainstream learning environment with a low student to teacher ratio; however, it is recommended to use behavioral technology in coordination with more typically teaching methods. Scores within the 0–2 range indicate that the child should primarily receive an individualized program with one-to-one direct instruction, use of behavioral technology, and sufficient oversight by qualified professionals (Sundberg 2014). Individual scores are transferred to the Scoring Form which is comprised of 18 individual smaller grids, separated by each barrier area, and can document scoring information for four testing administrations (Sundberg 2008).

Clinical Use

The VB-MAPP assessment is designed to identify skill deficits for learners with speech and language delays that impact their learning, regardless of age and/or diagnosis. Although a comprehensive knowledge of applied behavior analysis (ABA) and B.F. Skinner's *Verbal Behavior* (1957) are not required, it is important that the administrator understands verbal behavior at a basic level. Additionally, assessors should be able to identify any unintentional influences on responding evoked by inappropriate prompting procedures. Information obtained through the assessment will be beneficial for parents and educators in determining the learner's skill acquisition needs and barriers to learning, which guides the learner's educational team with planning for the individualized educational needs of the child.

Definition

Verbal communication refers to the production of spoken language to send an intentional message to a listener. Verbal and nonverbal communication abilities are considered to represent a core deficit in the diagnosis of autism. Indeed, the presence of fluent spoken language (in the form of regular and nonimitative use of multiword utterances) during the preschool years is a robust predictor of positive long-term outcomes for children with autism. In the research literature, the acquisition of fluent spoken language is sometimes referred to as functional speech. The domain of verbal communication can be divided into several component areas: semantics (vocabulary), syntax (grammar), and pragmatics (the social uses of language). Often, pragmatics is the area of spoken language that is most challenging for individuals with autism.

Verbal Comprehension

Definition

Verbal comprehension is the ability to understand spoken language. Early in typical development, a relative advantage of verbal comprehension over spoken language ability is observed when language abilities are measured using both parent report and direct assessment measures. An atypical profile of language comprehension and production has been reported for young children with autism by several groups of researchers. Two

atypical profiles have been described. In one profile, the relative advantage of receptive over expressive language is decreased (i.e., the receptive-expressive gap is smaller) for children with a diagnosis of autism, but not PDD. In the other profile, young children with autism actually demonstrate lower age-equivalent scores for language comprehension than they do for production. Many common assessment instruments include subtests designed to measure verbal comprehension of language, including the Vineland Adaptive Behavior Scales, the infant subscale of the MacArthur-Bates Communicative Development Inventory, the Preschool Language Scales, and the Mullen Scales of Early Learning. Other authors report that, in slightly older children with autism, verbal comprehension no longer lags behind expressive language in that standard scores for language comprehension are found to be commensurate with scores for spoken language. It has been suggested that the comprehension of language in a conversational context may provide challenges for individuals with autism that are not present within a standardized testing context. For example, the need to respond to non-verbal cues that support semantic meaning may interfere with the verbal comprehension ability of individuals with autism.

Verbal Comprehension Index

Definition

The Verbal Comprehension Index (VCI) is one of the indices representing the major components of intelligence in two of the Wechsler Intelligence Scales: the Wechsler Adult Intelligence Scale (WAIS) and the Wechsler Intelligence Scale for Children (WISC). It is thought to provide a relatively pure measure of verbal abilities, free of the influences of auditory attention and concentration. In the fourth edition of the WAIS (WAIS-IV), the VCI is comprised of three main subscales, with an additional supplemental scale: Similarities, which measures abstract verbal reasoning; Vocabulary, in which words must be defined singly, without context; Information, which tests general knowledge of history, art, culture, and politics; and Comprehension (supplemental), which measures the ability to understand abstract or idiomatic expressions. In the fourth edition of the WISC (WISC-IV), the VCI consists of the Vocabulary, Similarity, and Comprehension subtests, with Information and Word Reasoning, a task which provides clues leading to a specific word, as supplemental scales.

Research has consistently shown that children and adults diagnosed with Autistic Disorder generally obtain scores consistently lower on the VCI

than they do on nonverbal indices of the WAIS. In contrast, individuals with Asperger's disorder tend to earn their two highest subtest scores in Information and Vocabulary, reflecting the VCI as a relative strength.

Definition

Verbal fluency refers to the ability to spontaneously generate as many words as possible within a given time period, according to a set rule. There

are two types of verbal fluency that are commonly tested: phonemic fluency and semantic fluency. During a phonemic fluency task, a person is asked to generate as many words as possible beginning with a specific letter of the alphabet. During a semantic fluency task, the person is asked to generate as many words as possible from a specific semantic category (e.g., animals), irrespective of which letter of the alphabet the words begin with. Typically, there is a 60 s time limit to complete individual verbal fluency trials, and performance is the sum of correct words generated within the allotted time period. A number of different errors can be calculated, including repetition and intrusion errors. Two underlying abilities govern verbal fluency performance: clustering and switching. Clustering is the tendency to produce a set of words within a particular subcategory (e.g., farm animals on a semantic fluency task requiring animal words). Switching refers to the ability to shift from one subcategory to the next in order to maximize performance (e.g., shifting from farm animals to pets, once generation of farm animals slows). Performance on verbal fluency tasks is associated with frontal and temporal lobe functioning. Verbal fluency is impaired in individuals with high-functioning autism when their performance is compared to people without ASD. Conversely, individuals with Asperger syndrome appear to have intact verbal fluency abilities.

Verbal Intelligence

Michelle Dawson

Hôpital Rivière des Prairies, Centre de recherche du CIUSS du Nord de l'île de Montréal et département de psychiatrie de l'Université de Montréal, Montréal, QC, Canada

Definition

Verbal intelligence refers to specific human language-based skills which are considered to reflect latent general abilities. Despite historical disagreement about the precise place and fundamental nature of verbal intelligence, widespread agreement about its importance is evident in its omnipresence across all major hierarchical models of human intelligence. A person's verbal intelligence is assessed through performance on one or more specific tests involving receptive and/or expressive spoken language. While these tests assess a limited range of specific verbal abilities, they are also intended to estimate, or to contribute to an estimation of, a person's general intelligence. Verbal intelligence tests contrast with performance or nonverbal intelligence tests, which may in fact require verbal skills (e.g., the comprehension of spoken instructions) but primarily are considered measures of other abilities, such as visuospatial perception or processing speed. Scores on verbal and performance intelligence tests can be combined to generate full-scale IQ scores.

The use of vocabulary tests in assessing verbal intelligence is nearly universal. In these tests, individuals are asked to demonstrate their understanding of single words, for example, by providing a spoken definition, by indicating one of several presented pictures in response to a spoken word, or by naming a single picture. Other kinds of verbal intelligence tests, often administered in addition to vocabulary tests, require specific skills in a variety of areas. Examples include identifying associations between words (verbal abstract reasoning), providing factual responses to general knowledge questions, and demonstrating comprehension of social conventions and practical "common sense."

As is evident in autism research, verbal intelligence scores can be derived in many different ways and from many different tests. A single test of vocabulary, such as the Peabody Picture Vocabulary Test (PPVT) or its variants, may be used. Alternatively, intelligence test batteries combine several verbal subtests to produce a verbal index score or Verbal IQ (VIQ), as in Wechsler Scales and the Stanford-Binet. Some intelligence test batteries also provide abbreviated versions in which verbal intelligence scores are derived from a vocabulary subtest either alone or combined with another verbal subtest. It is important to note that tests which assess verbal intelligence are culture specific and evolve over time with respect to their specific content. Thus, whether a person has or has not been educated within a specific culture affects their measured verbal intelligence. What kinds of tests are or are not included when measuring verbal intelligence may also be subject to change. For example, Wechsler scales subtests once included as measures of VIQ were later indexed as measures of working memory (e.g., tests of arithmetic ability and digit recall).

Verbal intelligence scores can be reported as IQs or other standard scores, as percentiles, age equivalents, or raw scores. Developmental tests designed for infants and preschool children (e.g., Mullen or Bayley scales) as well as tests of adaptive behavior (e.g., Vineland) are commonly used to assess autistic individuals and include language-related domain scores. However, these reflect developmental or adaptive levels rather

than verbal intelligence. Further, the content of some language-related items in developmental and adaptive tests may be similar to diagnostic signs of autism and therefore overlap with items in autism diagnostic instruments.

Historical Background

Unusual patterns of verbal abilities are prominent throughout the first formal descriptions of autistic individuals. None of the 11 children described by Leo Kanner responded typically when spoken to; a majority presented as though deaf. The eight children who developed speech (with or without delays) and the three classified as mute did not, in Kanner's view, fundamentally differ in their failure to engage in appropriate verbal communication. The speaking children displayed immediate and delayed echolalia, reversed pronouns, and a lack of spontaneous or typically meaningful sentences. Words were used in idiosyncratic or rigid and literal ways. Strong rote memory was evident, as were verbal strengths in naming objects, using plurals and tenses, and reciting information within formats or categories (e.g., poems, psalms, the alphabet, lists of animals, and presidents). As Kanner (p. 243) observed, "long and unusual words were learned and retained with remarkable facility." In later papers, he acknowledged that seemingly irrelevant or nonsense utterances in fact conveyed meaning via metaphors and other atypical but decipherable verbal associations. While autistic children showed marked resistance to teaching, regardless they learned – displaying improvements over time including spontaneous nonechoed sentences with correct pronouns. Even "mute" autistics sometimes spoke in full sentences in emergencies (Kanner 1973).

The four autistic children described by Hans Asperger had verbal abilities at least as idiosyncratic as those encountered by Kanner. They spoke like adults, responded unpredictably or inappropriately – if at all – when spoken to, and were nearly impossible to teach. Both Kanner and Asperger relied far more on description than

test scores in assessing verbal abilities; both doubted that autistic children's intelligence could be fairly estimated via conventional testing.

In 1945, Scheerer et al. reported an extended case study of "L," an autistic savant (calendar calculation, music) who excelled in uninstructed memory of word, letter, and number sequences; and of names, places, and events associated with dates (e.g., birthdays). Several attempts to measure L's intelligence were made over time with varying degrees of success. As a child L – when testable – achieved normal range IQs but as an adolescent his Stanford-Binet IQ was 50. Verbal subtest performance ranged from strengths in immediate memory (of digits and sentences) to limited or idiosyncratic performance in tests of analogies, comprehension, reasoning, and vocabulary. For example, he defined "gown" as "something I have on" (p. 9). Aspects of information he processed well were deemed outlandish and irrelevant, while his unusual verbal abilities suggested that "rote memory without comprehension of social contents and symbols may operate astoundingly well" (p. 14) to the point that impairments are concealed.

Anticipating important directions in later research, Scheerer et al. also questioned Kanner's view of autism as primarily affective. Instead they proposed that L's strengths and deficits were underpinned by a fundamental inability to understand or form concepts, symbols, and abstractions. Similar views of autism flourished in the 1960s and 1970s, as summarized in Wing and Ricks' 1975 overview of language and communication in autism. Intelligence measures, including verbal tests, were important in the emerging characterization of autism as a cognitive phenotype. Hermelin and O'Connor (1970) reported a series of seminal experiments in which autistic and non-autistic children were matched according to intelligence test scores. In a core group of autistic children whose mean age was 10 years, performance scores (Merrill-Palmer) were higher than verbal scores (PPVT). However, two children had verbal age equivalents above 10 years, well exceeding their performance scores. Hermelin and O'Connor found that autistic children organize and recall verbal information atypically, with

diminished dependence on meaning, categories, and context.

Within the same time period, Rutter and colleagues published a series of papers reporting a longitudinal study of 63 individuals originally identified as autistic or “psychotic” in the 1950s. In adolescence (mean age 15 years), Wechsler scores ranged from untestable to above average. Performance (PIQ), VIQ, and full-scale means for testable individuals were all in the 70s – and in turn higher than receptive vocabulary (PPVT) and adaptive ability (Vineland) scores. More autistics had higher PIQ than VIQ compared to the reverse pattern, with a Block Design peak and a wide scatter of subtest scores (Lockyer and Rutter 1970). The highest verbal subtest score was Digit Span, the lowest Comprehension. Rutter (1966) noted that on verbal tasks, many autistics were untestable but a minority in contrast achieved their best scores, including three individuals where this unexpected pattern was “very marked.” Yet these three, one of whom excelled in math and music, still had low Comprehension scores and a history of “very backward speech development” (p. 73). Across the full autistic sample, 31 spoke by age 5 and 7 developed speech afterward, as late as age 11; one-third received no education whatsoever, while a majority received 2 years or less. Individual VIQ scores changed (both increases and decreases) on average 17 points from IQ approximations recorded at preschool age, but the group mean did not change.

To investigate the extent and specificity of verbal impairments in the autistic cognitive phenotype, Bartak et al. (1975) characterized and tested small groups of autistic and nonautistic language disabled (“dysphasic”) boys. All the children had PIQ scores of at least 70 and were matched on this measure. The autistic boys (mean age 7 years) were distinct from their controls in achieving mean Wechsler PIQ (94–97) which dramatically exceeded their Wechsler VIQ (67, when testable), PPVT (52), and Vineland (70) scores. Their distinctively scattered Wechsler subtest scores included a relative Block Design peak and a greater range within the verbal subtests, which included an extremely low Comprehension score. Interpreting this and his earlier

follow-up study, Rutter proposed a primary role for a severe distinctive verbal impairment in autism, with scattered PIQ subtest scores (e.g., high Block Design, low Coding) speculated to result from test differences in verbal loading.

A follow-up study of the boys in Bartak et al. (1975) into young adulthood found the autistics were distinctive in their trajectory of verbal abilities (Mawhood et al. 2000). Over time, the autistics’, but not the nonautistics’, Wechsler VIQ increased significantly – a group average of 16 points, with individual increases up to 50 points. The number of autistics who could be tested on all Wechsler subtests doubled (from 9 to 18, out of 19), while the PIQ-VIQ discrepancy was no longer significant. No subtest scores were reported. On PPVT, the autistic group also did significantly better over time, largely due to losses in the controls. While mean differences between the two groups had diminished, the autistic adults displayed much higher variation in scores on the verbal tests (Wechsler VIQ, PPVT).

Starting in the 1980s, studies using false belief and other social-specific tasks proliferated, raising questions about appropriate matching strategies and instruments, and whether inconsistent results could be attributed to inadequate accounting for group differences in verbal intelligence (Bowler 2007, for an overview). Meanwhile, studies including autistic Wechsler subtest and PIQ-VIQ profiles slowly accumulated, with 16 collected in Siegel et al. (1996), who also reported a new study. Overall, the PIQ-VIQ discrepancy pattern was inconsistent across studies. This is unsurprising given that the studies spanned 31 years, included very small samples across different age ranges, had different inclusion criteria, used different test versions, and encompassed different diagnostic definitions and practices. Nevertheless, Block Design robustly stood out as the highest Performance subtest score (all studies) and Comprehension was similarly robust as lowest Verbal score (all but one study).

The 1980s also marked the gradual introduction of Asperger syndrome as a separate autistic spectrum diagnosis, a change formalized in the 1994 DSM-IV, followed shortly by Klin et al.

(1995) report of no VIQ-PIQ discrepancy in autism, but a large Wechsler VIQ over PIQ discrepancy in Asperger syndrome. Ehlers et al. (1997) reported a similar result, with an Asperger subtest profile dominated by Verbal peaks (Vocabulary, Similarities, Information) and low scores in the Performance subtests Coding and Object Assembly.

While the views of autism touched upon above have fluctuated in their prominence or have been modified over time, the historical importance of verbal intelligence in autism research continues to the present. Thus verbal intelligence tests have been and continue to be used in cognitive profiles of autism: to assess different specific verbal abilities and to contrast verbal intelligence with other abilities. Verbal intelligence tests continue to be used as matching variables, as measures of changes in ability over time, in attempts to form or confirm autism subgroups, in case studies of individuals with exceptional or savant abilities, and as a way to differentiate autistic individuals from both the typical population and other atypical populations. Descriptions of aspects of autistic verbal abilities (e.g., lack of overt response to speech sounds; idiosyncrasies of speech such as pronoun reversal) that date back to Kanner's seminal observations remain important within diagnostic instruments and in characterizing developmental trajectories in autism.

Current Knowledge

Empirical Findings from Verbal Intelligence Tests

The diagnosis of autism is consistent with all possible levels of measured verbal intelligence. In other words, verbal intelligence in autism, as assessed via different standard measures, spans the full range from a VIQ of 150 or more to an assigned score of "untestable." High variance with respect to specific verbal abilities is durably characteristic of autism within and across individuals, encompassing multiple dimensions, and including sometimes dramatic incongruities between high and low abilities. Addressing such high variance by creating autism or autistic

spectrum subgroups is frequently invoked as a high priority, but as yet, little consensus as to valid subgroups has emerged. Widespread disagreement over how and whether to distinguish Asperger syndrome from autism has led to a welter of inconsistent findings regarding cognitive profiles, including patterns of verbal intelligence scores, across the autistic spectrum. DSM-IV autism subgroups, including Asperger syndrome, are now lumped together as a single autistic spectrum diagnosis in the DSM-5, where "with or without language impairment" is one of several specifiers but a history of speech delay is not considered.

However, regardless of diagnostic confusion and numerous other confounds (see "[Historical Background](#)" above), some findings persist, including autistics' difficulty with the Wechsler verbal subtest Comprehension. In a population-based study of school-aged children, Charman et al. (2011) found Comprehension scores significantly below Wechsler subtest means across various subgroups as well as in the full group of autistic children who were testable. No other finding involving Wechsler subtests achieved such consistency in the broadly defined autistic spectrum sample. Another persistent finding is adaptive ability scores which are lower than measured verbal intelligence, a discrepancy that can be extreme in autistic individuals with average or high VIQ scores. For example, in a clinic-based sample of autistic spectrum children and adolescents whose VIQ was at least 70, mean VIQ was 107 (range 70–150) in contrast with mean Vineland composite scores of 55 (range 25–79; Klin et al. 2007).

Large individual variations in trajectories of specific verbal abilities over time have also been reported as characteristic of autism. In a follow-up to mean age 29, Howlin et al. (2004, p. 219) reported "considerable movement in verbal IQ levels over time" in some individuals, with a small group-level improvement. Of the 68 autistics tested, 14 fell into the normal range of VIQ in childhood, while 32 scored at this level as adults. Thirteen of 31 individuals who as children had verbal intelligence scores of less than 30, or could not be tested at all, scored

significantly higher as adults – nine of them in the normal range. Neither verbal intelligence measured in childhood nor development of speech by 5 years of age – a milestone popularly claimed to be crucial – was a good predictor of a range of adult outcomes. A later follow-up of the same sample to mean age 44 found high variance in VIQ-PIQ discrepancies (from VIQ 50 points lower than PIQ, to 38 points higher) and a “small but steady increase” in VIQ across timepoints in testable individuals (Howlin et al. 2014).

In the same direction, Anderson et al. (2007) investigated verbal ability trajectories within childhood, starting from an original diagnosis of autism, PDD-NOS, or other developmental disability at age 2, to outcomes at a mean age of 9 years. Children were assessed with a mix of developmental and IQ tests. The main finding was higher variance in verbal ability outcomes in the autistic spectrum children, particularly those whose specific diagnosis was autism. In these children, “improvement can range from minimal to dramatic” (p. 594) with many trajectories collected at either extreme. While group mean verbal abilities were lower for autistic than nonautistic children, the exceptionally wide range of autistic outcomes was such that a greater number of autistic children achieved average level or better verbal intelligence scores at age 9.

Case studies of autistic individuals further add to the picture of remarkable variance in verbal intelligence and apparent incongruities across numerous dimensions. Autistics who have little in the way of functional speech and are therefore classified as “nonverbal” may also have high measured verbal intelligence. For example, Bonneh et al. (2008) report a Wechsler VIQ of 128 while Gernsbacher (2004) reports a PPVT standard score of 160, in case studies of minimally speaking autistic children tested respectively at 12 and 6 years of age. Conversely, a nonspeaking autistic adult is reported unscorable on PPVT, suggesting verbal intelligence so low it cannot be measured. However, he also has outstanding performance (estimated IQ of 140) on Raven’s Matrices – a general intelligence test which does not include verbal material yet for nonautistics requires verbal

abilities. The same autistic adult demonstrates outstanding calculation skills whose acquisition, even at a much more basic level, would depend on verbal abilities in nonautistics (Anderson et al. 1999). An incongruity between very low or untestable VIQ and normal-range or high Raven scores has also been displayed by some autistic children (Dawson et al. 2007; Courchesne et al. 2015). The important question of how to fairly assess verbal intelligence in minimally speaking autistics, who in addition may have difficulty pointing, has belatedly appeared in the literature (Kasari et al. 2013), but studies are as yet sparse and preliminary.

Underlying Abilities and Theoretical Accounts

With respect to early development, both echolalia and hyperlexia are well established as characteristic of autism and both indicate that autistics acquire verbal abilities in an atypical way. Autistics may enter into language by first learning its complex structure rather than by first learning its meaning, as is the typical pattern. For example, evidence suggests an early atypical developmental pattern of discrepantly high expressive versus receptive verbal abilities, at least in what has been considered the specific diagnosis of autism (e.g., Hudry et al. 2010). However, findings may be in part dependent on adaptive and parent-report measures, and again are within a context of high individual variance across all verbal measures.

Beyond early development, where autistics’ verbal abilities may be difficult to assess, numerous findings have confirmed that autistics of all ages perceive, organize, and recall verbal information in atypical ways. Autistics are characterized by strong phonological processing of language and by enhanced perception of speech. In neither case is there a consistently straightforward or predictable trade-off with other aspects of verbal information processing. Exceptional absolute pitch for speech, for instance, has been found in an autistic individual with a characteristic delay in speech development – but the person went on to become fluent in numerous languages (Heaton et al. 2008).

In addition, although autistics may organize and recall verbal information without using typical categories, they are also capable of forming categories when instructed to. The typicality, or not, of category formation displayed by autistics thus has depended on specific task instructions (Bowler 2007). Similarly, autistics' use of context when processing verbal information atypically encompasses both local (e.g., immediately proximate) and global (e.g., sentence-level) contexts. This does not imply an inability to use wider contexts but does demonstrate that more immediate contextual possibilities are not discarded via typically mandatory top-down processes (Henderson et al. 2011). In turn, this is consistent with the idiosyncratic use of language in autism, including unusual vocabulary and word associations. Further in this direction, autistics show a consistent pattern of difficulty with episodic but not semantic verbal memory, and also difficulty with organizing verbal information into expected, typical narratives (e.g., Diehl et al. 2006). Autistics would therefore be expected to perform poorly on tests which require verbal information to be organized into conventional or "common sense" type narratives, as in the Wechsler Comprehension subtest.

Overall, existing findings suggest that aspects of verbal information which automatically take precedence in nonautistic information processing hierarchies do not play the same role in autistics (Mottron et al. 2006). For autistic individuals, depending on circumstances and task demands, this may result in both advantages and disadvantages, which in turn are evident in uneven development and verbal intelligence profiles within and across individuals.

Future Directions

- Individuals diagnosed with neurodevelopmental genetic syndromes (e.g., fragile X, Williams syndrome) may also meet autism criteria on various instruments. Whether these individuals are in fact autistic is an increasingly important research question which cognitive

profiles, including verbal intelligence measures, may help address.

- The challenge of fairly testing verbal intelligence in all autistics, including those with atypical or minimal speech, was apparent in the first published descriptions of autism. Despite progress in technology – touch screens, smart phones, tablets, applications – this area remains neglected.
- New technologies should also be explored as opportunities for autistics to develop and display verbal abilities. For example, given the opportunity, autistics may demonstrate their ability to learn and adapt technologies for communication in both expected and unexpected ways.
- There has been little interest in the atypical kinds, quantities, and arrangements of information – including verbal information – from which autistics learn well. Availability (or not) of verbal information remains overlooked as a plausible factor in the high variance of verbal abilities in autism.
- Autistics with excellent adult outcomes, but atypical development and patterns of specific verbal abilities, have appeared in the literature throughout autism research history. Yet these individuals, and the patterns of verbal ability associated with successful autistic outcomes, remain understudied.
- The relationship between speech delay and later verbal intelligence, including in adulthood, remains understudied. Whether longer or shorter or no speech delay, or for that matter precocious speech, consistently leads to better or worse verbal (and other) autistic outcomes is an important but neglected research question.
- High variance in verbal intelligence is widely regarded as an obstacle to autism research which ideally should be eliminated through subgrouping. However, attempts to compose consensual autism subgroups have not been successful. One future direction is to consider high variance in verbal outcomes not as an impediment to research but as informative about the nature of autism and the possibilities of autistic individuals.

Definition

Verbal semantic coherence refers to the ability to use the broader context of a story or sentence, and the semantic relationships between words to aid understanding and interpretation of spoken and written language. The concept of verbal semantic coherence stems from Weak Central Coherence Theory, which posits that individuals with autism spectrum disorder (ASD) have a cognitive style that involves detail-focused processing, rather than global or gist processing of information. In other words, people with ASD are more likely to see the individual trees rather than the forest. This detail-focused cognitive style has been observed while individuals with ASD engage in verbal tasks. Examples of impaired verbal semantic coherence in autism include difficulties using sentence context to interpret the meaning of homographs and heteronyms (words with one spelling, but two meanings and two pronunciations), poor recall of semantically related words, difficulties

Vestibular Function in Children with Autism

Definition

Vestibular function refers to the ability to maintain balance and postural control, a stabilized vision during head movements, and spatial orientation. The vestibular system is a complex sensorimotor system which comprises the peripheral vestibular apparatus or labyrinth, the postural muscles, visual system, brainstem, cerebellum, and the cortex. The peripheral portion of the vestibular system is located in the inner ear and consists of three semi-circular canals and two otolith organs (i.e., saccule and utricle) providing complementary information about rotational and translational head movements relative to gravity. It gives together with centrally integrated proprioception and visual stimuli an internal representation of the environment and movements through it. In addition, a stabilized vision during head movements and postural control are reflexively maintained by the vestibulo-ocular, vestibulospinal, and vestibulo-collic reflexes. In case of a dysfunction in this complex system, postural imbalance and dizziness are often the most reported complaints in adults. In contrast, these symptoms are frequently underestimated in children, since children are often not able to communicate their complaints properly and a vestibular impairment often has a different clinical course compared to that in adults. Nevertheless, when a vestibular dysfunction occurs at birth or in early stages of life, an impact on motor, cognitive,

psychosocial, and educational performances may be expected.

Similar to children with a severe vestibular dysfunction, children with autism often present with vestibular-related complaints such as avoidance behavior, gross and fine motor impairment, static and dynamic postural instability, delayed motor milestones, and/or poor motor coordination. Additionally, compared to typically developing children, research indicated that postural performances in children with autism were found to be the most aberrant in conditions where they could rely on their vestibular input only, which is also suggestive for a vestibular deficit. Therefore, it has been suggested that a (peripheral or central) vestibular dysfunction may contribute to the phenotype or behavioral features in a subset of children with autism spectrum disorder, which has been supported by studies using vestibular function testing in this population. Moreover, some children with autism are known to have a preoccupation with spinning objects or repetitive movements, such as spinning or shaking their head or have difficulties in integrating vestibular input. However, due to heterogeneous findings in studies mainly focusing on the function of the horizontal semicircular canals only (only one fifth of the peripheral vestibular system), a more extensive and objective elaboration on whether an accompanying vestibular dysfunction is present in this population is highly recommended.

Vestibular System in Autism

Edward Ritvo
UCLA School of Medicine, Los Angeles, CA,
USA

Definition

Vestibular System

A system in the body that is responsible for maintaining balance, posture, and the body's orientation in space. This system also regulates locomotion and other movements and keeps objects in visual focus as the body moves.

The vestibular system is comprised of the vestibular apparatus itself, the vestibulocochlear nerve, and those parts of the brain that interpret and respond to information derived from these structures.

Historical Background

Abnormal modulation of sensory input (over and under responding) has been a pathognomonic feature of autistic disorder (AD) since it was first described by Kanner (1968). Of particular note is the fact that response levels may not remain

static, but can alternate over time in the same individual. This characteristic, called “Perceptual Inconstancy” (Ornitz and Ritvo 1968) underlies the diagnostic criteria for AD listed in the DSM-IV-TR (American Psychiatric Association 2000) as, “stereotyped and repetitive motor mannerisms” (e.g., hand or finger flapping or twisting, or complex whole-body movements). The proposed DSM V (American Psychiatric Association 2010) lists these symptoms as, “Hyper- or hypo-reactivity to sensory input or unusual interest in sensory aspects of environment; (such as apparent indifference to pain/heat/cold, adverse response to specific sounds or textures, excessive smelling or touching of objects, fascination with lights or spinning objects).”

Abnormal modulation affects all sensory systems (Ritvo 2006; Leekam et al. 2007; Schoen et al. 2009, DSM-IV-TR and proposed DSM 5, Reynolds and Lane 2008; Minshew and Hobson 2008), for example, many AD infants and children are initially referred for evaluation of possible deafness. These children may not respond at times to speech or loud noises, and at other times cover their ears and cry in response to soft sounds. Alternating sensitivity to temperature is shown in AD children who demand wool sweaters and heavy coats in the summer, but will only wear light skimpy clothes in the winter. Response to pain varies from ultra sensitive to nonexistent, even with major injuries. Visual detailed scrutiny may alternate with bumping into things as if they were not seen. Hypersensitivity to the texture of food is responsible for the often-reported behavior of spitting out lumpy items, a problem many parents solve intuitively by using a blender. And, lastly, many AD children become preoccupied with obtaining certain specific odors, while at other times will ignore noxious fumes.

Current Knowledge

Symptoms Due to Abnormal Modulation of Vestibular Input

Under responsiveness to vestibular input leads to several types of repetitive behaviors. For example, many children and adults with AD spend hours

each day on swings, jumping on trampolines, and twirling themselves around. They do this without becoming dizzy or nauseous, and report that it is “soothing” and “comforting” (Ritvo 2006).

Staring at rotating objects such as phonograph records and fans, head shaking, body rocking, and finger flapping in front of the eyes are other common ways AD individuals induce nystagmus and vestibular input.

Over responsiveness to vestibular input leads to the opposite kind of behaviors. Maintaining rigid postures, placing themselves in unusual prone or upside down positions, refusing to get out of bed, and hiding in dark places are behaviors that AD individuals use to diminish vestibular input and maintain equilibrium.

Symptoms due to both over and under modulation of vestibular input, like those in the other sensory systems, tend to decrease in frequency and duration with age, although, in some, they remain lifelong (Ritvo 2006).

Neurophysiologic Studies

Several neurophysiologic studies begun in the 1970s attempted to identify objective measures of abnormal vestibular processing. One pilot study identified a subset of AD children who showed decreased post rotator nystagmus (PRN) in the light, when visual fixation is possible, but not in the dark (Ritvo et al. 1969). However, replication studies failed to identify specific PRN differences between large groups of AD and age and sex matched non-AD children that could be of diagnostic significance (Ornitz 1970). A review of the recent literature failed to find subsequent studies that identified specific pathology in the vestibular system (peripheral or central) pathognomonic of autism, but concluded that more research in this area is warranted by previous findings (Rogers and Ozonoff 2005; Reynolds and Lane 2008).

Therapeutic Implications of Abnormal Vestibular Modulation

Based on the clinical observations of Jane Ayers in the 1970s (Ayers 1974), occupational therapists and sensory integration therapists developed interventions aimed at assessing and improving symptoms of abnormal vestibular modulation.

These interventions have gained worldwide application based on positive clinical experience, but to date no objective studies of their efficacy have been published (Kinnealey et al. 1995; Watling et al. 2001; Tomchek and Dunn 2007).

Victimization

Guillermo Montes

St. John Fisher College, Rochester, NY, USA

Definition

There is no consensus on what victimization is or what it should cover. The dictionary definition includes victimization of crime, of unjust punishment and of fraud. Victimization is often classified by the source of the offense or the nature of the attack. Two forms of victimization receive disproportionate amount of attention by the research community, child abuse and peer victimization or bullying, while other forms of victimization are not systematically studied. This entry deals with those unstudied sources of victimization following the dictionary definition of crime, unjust punishment, and fraud.

Historical Background

Although undoubtedly victimization of persons with ASD is as old as the disease itself, there has been and continues to be an almost complete paucity of research on the topic.

Current Knowledge

Much of what is known about criminal victimization is not specific to persons with ASD. People with disabilities are two to three times more likely

to be victims of violent crime (rape/sexual assault, robbery, simple, and aggravated assault). In addition, people with ASD are also at higher risk of financial exploitation (Volkmar et al. 2005). About 15% of crime victims with disabilities report that they suspect they were targeted because of their disability (Harrell and Rand 2010). Because of their inability to perceive or understand social clues, people with ASD have been called the “perfect victims” (Debbaudt 2002).

Victimization by direct caregivers (e.g., parents) is often treated as a form of child abuse, although such victimization may occur beyond the age of 18. Peer victimization has been studied repeatedly mostly among children with ASD in the school context (see “► Bullying”). Little is known about peer victimization among adults with ASD.

Victimization by educators and professional caregivers was recently documented in a report from the US Government Accountability Office on the use of seclusions and restraints that resulted in deaths or abuse (United States Government Accountability Office 2009). Given that there is no systematic research on victimization by school personnel, the prevalence of this form of victimization is unknown.

Additionally, persons with ASD can be victimized by law enforcement. When the police comes into contact with persons with ASD spectrum disorders because they are witnesses, perpetrators, or victims of crime, untrained officers can easily mistake ASD symptomatology for suspicious behavior. ASD symptomatology (e.g., absence of eye contact, repeating what an officer says, not understanding body language, not following commands, confessing to crimes they did not commit, persistent interest on aspects of a situation others believe irrelevant) can be easily confused with indications of guilt by officers unfamiliar with ASD during informal questioning, arrest, and formal interrogation. Sometimes such mistakes may lead to criminal convictions of innocent persons with ASD disorders; other times the information provided by a person with ASD is thought to be unreliable (Debbaudt 2002). Consequently, the Federal Bureau of Investigation and a number of ASD advocacy organizations (in particular the Autism

Society) are working with police and other first respondents to educate them about ASD (Debbaudt and Rothman 2001).

As is the case for many other people with incurable diseases, many persons with ASD and their families become victims of those who market untested remedies and effective treatments or cures for ASD. Distinguishing between legitimate and responsible complementary and alternative medicine (CAM) practice and quackery can be very difficult, particularly for desperate parents of children with ASD at a time when the use of CAM is increasing among the general population. Quackery is characterized by exaggerated claims about the likely benefits of the product or service for the typical patient, as well as its higher likelihood to result in financial, emotional or physical harm, including unwarranted delays in seeking appropriate diagnosis and treatment.

In the United States, both the Federal Drug Administration and the Federal Trade Commission have responsibility for consumer protection, yet both agencies lack adequate resources to police the many attempts to promote services and therapies of questionable value to people with ASD. In rare cases, the FDA or the FTC has sent warnings to marketers of unapproved therapies or products (e.g., unapproved chelation products (Federal Drug Administration 2010)). Yet, many CAM approaches are outside of the jurisdiction of the FDA and current regulatory practice in the United States requires the government to prove evidence of harm. Additionally, many of these approaches are not subject to adverse event reporting of any kind. Thus, it is unsurprising that many cases of misrepresentation of alleged benefits are not investigated or prosecuted, as they often go unreported by the victims. As in other forms of victimization, there are no scientific studies on the prevalence and nature of financial, emotional, or physical harms that occur due to quackery, nor any studies to determine if people with ASD or their close relatives can distinguish between legitimate CAM and quackery. There are however many published accounts showing that quackery and charlatanism related to ASD therapies and

“cures” is widespread (Fitzpatrick 2008; Offit 2008; Schreibman 2007).

Finally, persons of ASD are also victims of fraud when researchers commit scientific misconduct on ASD-related studies. The most famous cause was the Andrew Wakefield’s 1998 study published in *The Lancet* expressing concerns that the MMR vaccination was linked to ASD. The dissemination of the claim through the media resulted in a loss of confidence in the MMR vaccination program in the United States and United Kingdom. For many families with children with ASD, the study also became a justification to seek treatment and cures outside of the medical establishment, thus delaying appropriate and timely treatment and exposing them to an increased risk of financial, emotional, and physical harm. In addition, many families decided not to vaccinate children who did not have ASD for fear of contracting ASD. In 2004, many of the Dr. Wakefield’s coauthors retracted the problematic interpretation (Murch et al. 2004). The UK’s General Medical Counsel erased Dr. Wakefield’s name from the medical register in 2010 and the original paper was subsequently retracted from *the Lancet* (Greenhalgh 2010).

Future Directions

There is no question that persons with ASD are at higher risk of various forms of victimization, yet scientific studies have not been systematically conducted to determine the prevalence of the various types of victimizations for persons with ASD and their families. With the exception of bullying and child abuse, there are no systematic efforts to determine the prevalence, causes, and remedies of the various forms of victimization presented in this entry. People with ASD will continue to be at higher risk of these various forms of victimization until studies elucidate their plight.

and a toy truck with which to play, but then pushes the toys away without making a choice. Simply replaying the video would be feedback and probably ineffective, so a replay would be used as an opportunity to teach an adaptive response. Thus the feedback itself might not be educational or therapeutic, but may serve to present “teaching moments,” which may be effective if developmentally appropriate.

Video feedforward entails the portrayal of an event as a future success, beyond current capability, achieved through filming and editing techniques. That is, a person will see a video of themselves succeeding in something where they normally fail. For example, the child above would be also be offered, say, a truck, filmed from a different angle, maybe even prompted to say “thank you.” The separate shots are then edited together to show the child adaptively choosing and receiving a toy, in this case, a truck. So the “teaching moment” is shown on video and the feedback errors are not used.

Thus feedback is effective when it allows feedforward to take place, either through additional training or therapy or through appropriately recorded and edited video. With individuals for whom learning comes easily, just seeing and hearing the video may be enough to create spontaneous feedforward and future adaptive responses to the event.

Video Feedback and Feedforward

Definition

Video feedback entails the replay of a recorded event with the intent that participants will learn improved behavior for that situation. For example, a child may be offered a choice of a toy bear

Historical Background

The first use of the term “feedback” was in the 1920s, in reference to that dreadful oscillation in sound systems turned in on themselves. Then feedback progressed through physics and biology, later psychology and education, to reference information about the impact on the environment of systems and organisms, and then the potential influence of that information in a “feedback loop.” The Concise Oxford Dictionary (2006, p. 521) defines feedback in psychology and biology as the “modification or control of a process or system by its results or effects.” A common biological example is the blink reflex, by which the eyelid moistens a drying eyeball. Examples in psychology are seldom so

clear cut. Feedback is routine in sports, where a video may be shown with analysis of what worked and more emphasis on what did not work. Any feedback may be disputed or have a negative emotional impact. To be used constructively, is it still feedback? Or does it become “feedforward?”

Feedforward is even more recent terminology. Although the terminology was not used, the concept had its most famous exploration in the 1940s by British air force scientists, led by Norbet Wiener. London was being attacked by German aircraft who tried to make their approach unpredictable with sudden changes of speed and direction (see Galison 1994). Wiener developed systems to predict the unpredictable so that a missile could be launched to intercept the plane on its future path. It was not until the 1970s that cybernetics embraced feedforward (e.g., Lee 1980) and psychology flirted with it (Björkman 1972). In cognitive behavioral psychology, feedforward is recognized as a personal image of future successful behavior, not previously achieved (Dowrick 1991, 2012).

Current Knowledge

Video feedback. While there are many studies using different forms of video with individuals with autism, there are not many using video feedback. For example, a review in 2005 (Ayres and Langone 2005) of 15 studies for social and daily living skills in children with autism, all used variations of video modelling, not feedback. There were peer and self-models, adults, multimedia, and point-of-view modeling. All were successful, although it should be noted that most included other strategies such as discussions and prompts. None used video feedback. More recently, a study by Robinson (2011) found video feedback effective in interventions with the communication skills of four young boys with autism – when the video was used with paraprofessionals delivering the skills training – not used with the children.

Lofthouse et al. (2012) list 19 “complementary and alternative treatments for autism,” from melatonin and B12 to acupuncture and massage. There is no mention of “video feedback,” either because it is “mainstream” rather than

“alternative” or because there are no reports of it. The review notes the “most empirical support” for (mainstream) applied behavior analysis. However, that requires “30–40 h of treatment per week for several years,” thus the impetus for alternative treatments.

There are studies using oral or social feedback but with little promise (unless one considers reinforcement “feedback”). For example, Bedford et al. (2013) found a failure to learn from social feedback in children with autism who had been held back in their vocabulary development around age 2 years. However, they did not mention the use of video or other possibilities.

Reviews of video feedback with general clinical populations do not help with autism. For example, there are numerous reviews of Video Interaction Guidance (e.g., Kennedy et al. 2011) around issues of interest in autism – for example, family studies including child clinical participants. But neither the data nor the references seem to mention “autism.” The authors do provide overall evidence that video feedback can be used effectively to improve parenting skills and parent–child interactions. It seems likely that video feedback, when used constructively for parenting, classroom management, etc., can benefit children and adults with autism. But there is little evidence that video feedback can benefit individuals with autism directly for skills or behavior development, unless it provides feedforward.

Video feedforward. Previous studies have demonstrated the effectiveness of video feedforward to improve various psychological conditions, for example, reading skills (Dowrick et al. 2006; Robson et al. 2015), sport performance (Ste-Marie et al. 2011), communication (Smith et al. 2014), and presentation skills (Murphy and Barry 2016). These are self-modeling interventions that acknowledge the procedure as “feedforward.” Most studies have focused on primary school-age children, often children with special needs, although some have included adults (see Dowrick 2012) and those with elite skills, such as gymnastics (Dowrick 1989) and swimming (Clark and Ste-Marie 2007). In a thesis study of four children aged from 9 to 17 years, Holly Smith produced remarkable results using video feedforward. The youth were all on the autistic spectrum, some severe, with serious phobias

of dogs. At first, two were treated with peer models, two with VSM: the first showed no effects; the second, moderate effects. Then all videos were redone to feature feedforward – with immediate and dramatic results. Phobic reactions disappeared, replaced by enjoyment, in some cases patting the test dogs and one request to own a similar dog (Smith 2018).

In all conditions, the *speed* of behavior change is most notable. In particular, the children with autism in the Smith et al. study, mentioned above, transformed their ability to use picture communication in a matter of days or short weeks. Such communication had previously proved so challenging, they had not gained skills in years of instruction.

Dowrick et al. (2006) implemented video feedforward on children with special needs who have difficulties in reading. Robson et al. (2015) support Dowrick et al.'s (2006) findings by showing the benefit of video feedforward on reading fluency. The participants were 11 children who watched the edited video of themselves reading fluently. The findings showed that feedforward helped them to read more fluently, as measured by accuracy, comprehension, and speed.

Ste-Marie and colleagues (2011) expanded the use of video feedforward to help children improving their performances in sport, including trampoline skills. Smith et al. (2014) used video feedforward to enhance the picture-based communication skills of two children with autism and one adult with Down syndrome in their social environments. Furthermore, Murphy and Barry (2016) showed video feedforward contributions in improving presentation skills of university students. Those findings indicate that video feedforward has been used in various settings for target behaviors which show promise for further research and applications to expand the use in other psychological aspects and settings.

Future Directions

Recognition of feedforward will improve as more self-modeling studies acknowledge the “feedforward”/“positive self-review” distinction. Clearly, interventions with feedforward show

remarkably superior speed and efficacy of behavior change. The literature will be notably advanced by the proper recognition of feedforward as distinct from the carefree or careless reference to feedback as a catch-all category for all video or other recorded replay.

Video Games and Violence

Laurie A. Sperry
Department of Psychiatry, School of Medicine,
Yale University, New Haven, CT, USA

Definition

Adolescents with autism spectrum disorder (ASD) spend a considerable amount of their leisure time playing video games to the exclusion of other pursuits. Often the content of these games is violent. It is unclear what impact the consumption of violent video games (VVG) has on the behavior of adolescents with ASD or whether this results in increased risk for contact with the juvenile justice system (JJS).

Historical Background

Following the mass shooting of children and school personnel in Newtown, Connecticut,

there is an emerging body of research specifically focused on video game use in children and adolescents with ASD. The shooter, Adam Lanza, was a young man with ASD who was known to play violent video games for several hours a day, including a first-person-shooter game entitled *School Shooter* (Sedensky 2013). The object of *School Shooter* (Checkerboard Studios 2011) is to murder as many schoolchildren and staff members as possible, using weapons similar to those utilized in the Columbine massacre. After completing the shootings, the gamer is prompted to commit suicide before being apprehended by law enforcement. Adam Lanza walked into Sandy Hook Elementary School, shot and killed 20 schoolchildren and six staff members, and then committed suicide prior to being apprehended by police. Norwegian mass shooter Anders Breivik received a diagnosis of ASD after murdering 77 people. Breivik wrote in his 1500 page manifesto that he utilized the video game *Call of Duty: Modern Warfare 2* and *World of Warcraft* as training videos for the attack. He photographed himself dressed in garb emulating characters from the games including a military uniform, a hazardous material suit, and a special operations soldier. At his trial, he made a statement related to how history would view him which was very similar in nature the script from the game *Call of Duty*. He reported playing both games for up to 15 h a day in preparation for the massacre (Breivik 2009). This raises the question, are violent video games serving as video model for mass shootings perpetrated by people with ASD?

Adolescents with autism spectrum disorders (ASD) spend approximately 4.4 h per day watching television and playing video games. This amount is greater than the time spent pursuing any other leisure activities (Mazurek and Wenstrup 2013). Parents reported considerable difficulty related to the behaviors displayed by their children with ASD when efforts were made to monitor and/or restrict access to media and video games. Longitudinal research by Willoughby et al. (2012) on the effects of VVG consumption on behavior in neurotypical adolescents suggests that continual violent video game play predicts the slope of aggression at a level reaching statistical significance. Moreover, sustained playing of

violent video games reliably predicted higher levels of aggression over time. Their findings suggest that continual nonviolent video (NVG) game play does not significantly predict scores of aggression.

There is limited research that focuses specifically on adolescents with ASD and the relationship between VVG and aberrant behavior. What is unknown is what effect the amount of VVG consumption has on measures of maladaptive behavior in adolescents with ASD and contact with the JJS. Maladaptive behaviors are defined as behaviors that impede participation in activities of daily living and may include property destruction, non-compliance, withdrawal, self-injury, and aggression (Shattuck et al. 2007).

Current Knowledge

Vulnerability to the Impact of Violent Video Games

Specific cognitive, social, and sensory functions are involved in the interaction with video game play (Durkin 2010). Each of these areas is impacted when a person has a diagnosis of ASD (DSM-5, APA 2013). Markey and Markey (2010) examined the personality traits that may make an individual more vulnerable to the effects of violent video games (VVGs). These researchers posited that preexisting dispositions increase the susceptibility of certain individuals to the impact of VVGs. Using the five-factor model of personality traits (McCrae and Costa 1999), they developed a spherical model to determine how the confluence of specific traits may render a person most vulnerable to the deleterious effects of VVGs. The model suggested that three orthogonal traits were moderating variables of VVGs. These traits included high neuroticism, low levels of agreeableness, and low conscientiousness. It is possible that the corollary to this model in the population of people with ASD is ToM deficits, belief persistence, difficulties with syllogistic reasoning, and difficulties with emotional regulation. As a result, they may be particularly susceptible to allegory or images of violent hyperbole, and it is possible that they may take the visual information presented in a VVG at face value and emulate

it. Comorbid psychiatric disorders could potentially serve as a moderating variable exacerbating the person's susceptibility to VVGs.

Violent Video Games and Aberrant Behavior

Anderson et al. (2004) completed a meta-analysis on the robust body of literature that demonstrates a relationship between consumption of virtual violence and actual aggression. The mechanism that accounts for this relationship is the subject of intense interest. A possible explanation for the relationship between VVG and increases in measures of aggression is that virtual violence is abstract and therefore pleasurable, allowing for a level of moral disengagement with violent actions. Many gamers describe a lack of remorse over engaging in virtual violence and derive great pleasure from playing VVGs (Ladas 2002).

As computer graphics become more sophisticated, the characters, both protagonists and antagonists, become more identifiable as social entities. These enhanced graphics allow for a level of immersion that has been linked to heightened enjoyment in game play (Skalski et al. 2006). Some VVGs come with a "blood on" feature, which allows the gamer to control whether they see the results of their carnage. Research has demonstrated that the "blood on" condition results in higher scores on measures of aggression than the "blood off" condition (Farrar et al. 2006). Hartmann and Vorderer (2010) have hypothesized that enjoyment of virtual violence may be contingent upon maximizing rewarding aspects of the game (feelings of power and/or success) while minimizing negative costs (guilt). This cost-benefit equation is likely impacted by both the amount of play and the role violence itself plays within the game. High-use gamers may become inured to images of violence and the resultant suffering displayed within the game (Carnagey et al. 2007). Gamers who are able to justify their behaviors because the antagonist is engaging in morally reprehensible acts may feel absolved of the guilt and distress associated with acts of virtual violence (Opatow 1990).

Another possible antecedent to this increase in aggressive behaviors may be the denial of humanness to the victim. Greitemeyer and McLatchie (2011) examined the role ascribing

or denying humanness to the victim in video games played in measures of violence and aggression. Visual hyperbole is often used to portray the antagonists in VVGs. These larger-than-life characters are imbued with nonhuman characteristics which may lead to the gamer engaging in cognitive distortions, allowing themselves to justify the intensity of their game-playing violence to vanquish the enemy (Smith et al. 2003). Greitemeyer and McLatchie (2011) hypothesized that this dehumanization and justification of violence could transfer from the screen to real life through the type of moral disengagement that assuages guilt and provides a pathway for aggression toward victims (Bandura et al. 1996).

These concepts of desensitization, feelings of power, and denying humanness to victims may have particular relevance to gamers with ASD. Many adolescents with ASD have been the victims of bullying and marginalization (Little 2002). They spend the majority of their leisure time playing video games that may provide their sole source of feelings of empowerment. In the game *One Life* (Chalk 2015), an FPS game, players only have one life and losing it means they are locked out of the game forever. This adds an element of reality to game play heretofore unseen. Players also have the ability to extend mercy or humiliate their victims prior to vanquishing them. The game boasts that no other game will provide players with the feelings of power and control over others. Players are rewarded for ignoring the cries of pain, rage, and appeals for mercy from their victims. In an ultimate act of degradation, players can urinate on their victims. From a behavior analytic perspective, the immediate and continuous schedules of reinforcement for aggression followed by intermittent schedules of reinforcement as the gamer advances through levels have the potential to build extremely durable aggressive mind-sets for the gamer with ASD.

People with ASD often have a concrete and literal sense of right and wrong and as such may find it easier to morally disengage than the neurotypical gamer. The ability to morally disengage requires the gamer to deny humanness to the victim, an act that is facilitated by viewing the

victim's acts as repugnant, thus justifying the vanquishing of the victim. This abates feelings of guilt and distress associated with virtual violence (Hartmann and Vorderer 2010).

Greitemeyer and McLatchie (2011) completed a series of two experiments designed to determine if type of video game (violent, neutral, pro-social) impacted measures of aggressive behavior. Playing VVG increased dehumanization toward others and was linked to increased measures of aggressive behavior. Specifically, the researchers found that players of VVG ascribed fewer human-centric emotions to others, reducing the opposing gamers, in a sense, to the level of animals, machines, or objects. This concept has interesting implications for gamers with ASD, many of whom experience difficulty in facial emotional recognition as the result of the social difficulties inherent in their diagnosis (O'Connor et al. 2005).

The role of VVG as a factor in conferring increased risk of aberrant behavior in adolescents with ASD is unclear. The answer to this question may serve to explain the distress and problem behavior exhibited by people with ASD when efforts are made to place parameters on their gaming (Mazurek and Wenstrup 2013). Engelhardt et al. (in press) recently completed a study in which adults with ASD as well as adults who were neurotypical were randomized to different video game playing conditions: VVG versus NVG. Measures of aggressive thought accessibility, aggressive affect, and aggressive behavior were taken following the consumption of VVGs. Compared with their neurotypical peers, adults with ASD were not differentially impacted by viewing VVG (Engelhardt et al. in press). These findings may have limited applicability to the current study as the adults were exposed to only three brief video game sessions (15, 10, and 10 min) for a total of 35 min of game play, and this figure is considerably less than the average 2.4 h of daily game play reported by parents of teenagers with ASD (Mazurek and Wenstrup 2013). Therefore, there may be something of a dose-response relationship in which long-term consumption of VVGs has a different effect on gamers with ASD than acute, short-term consumption.

A study by Krcmar and Lachlan (2009) examined the association between length of VVG play and aggression and found a positive relationship between habitual game play and physical aggression. A study which examined the impact of VVG on measures of aggression found that there were significant increases from pre-exposure baselines after participants played first-person-shooter games (Barlett et al. 2007). Thus, long-term exposure to violent images may lead to an increase in aggression as the result of regularly primed aggressive mind-sets.

A pilot study examined the relationship between amount of VVG consumption, scores on the subscales of the Aberrant Behavior Checklist (ABC), and contact with the JJS in a group of adolescents with ASD and comorbid psychiatric conditions who were placed in a Neuropsychiatric Special Care Unit (Sperry 2016). There was a considerable range in the amount of weekly game play (3–28 h per week) with an average of 8.5 h. The majority of these games (67%) contained violent content. There was no statistically significant relationship between amount of VVG and contact with the JJS which may be a function of the NSC serving as a diversionary, alternative placement to the JJS. Parents setting limits on the video gaming were consistently listed as precipitating factors in the outbursts that led to placement in the NSC. Adolescents who played the most violent games the most frequently had the highest scores on the ABC subscales of hyperactivity, irritability, lethargy/social withdrawal, and inappropriate speech.

Internet Addiction

There is a growing body of literature on the Internet gaming disorder (IGD), which has been identified in the emerging measures and models section of the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* as a disorder that merits additional clinical research prior to being included in the main text (American Psychiatric Association 2013). People with IGD experience clinically significant levels of distress when limits are put on their gaming, but they also experience this distress when playing compulsively, which

compromises other activities of daily life including work and school.

In one of the largest studies to date ($N = 7069$), Grüsser et al. (2006) found that nearly 12% of study participants met diagnostic criteria for addiction (including craving, feelings of relief when playing, and increasing game play) relative to their gaming behaviors. Based on their responses to an online questionnaire, participants fell into two groups: pathological gamers who played an average of 4.70 h per day and non-pathological gamers who played an average of 2.49 h per day. There were statistically significant between-group differences, with the pathological gamers reporting greater anticipated relief of withdrawal when playing. They also demonstrated statistically significant higher levels of craving than non-pathological gamers. Addiction may be the result of the neurological response to the positive reinforcement inherent in the games and the success the individual experiences while playing. During their time away from gaming, they experience feelings associated with drug withdrawal.

Circumscribed interests may be part of the constellation of characteristics that can render people with ASD more vulnerable to the impact of VVG. Klin et al. (2007) first posited the idea that video game addiction may be an example of a circumscribed interest. In a study by Romano et al. (2014), the relationship between scores on the autism spectrum quotient questionnaire (AQ; Baron-Cohen et al. 2001), scores on the Spielberger trait anxiety inventory (STAI-T; Spielberger 1983), scores on the Beck depression index (BDI; Beck et al. 1961), and scores on the Internet addiction test (IAT; Young 1998) were examined. The IAT measures the extent to which activities of daily living are compromised by time spent on the Internet. Statistically, significant relationships were found between scores on the AQ, STAI-T, and degree of Internet addiction. People with higher AQ scores, meaning they had more autistic traits, tended to score high on the IAT with anxiety serving as a moderating variable. Interestingly, participants with high AQ scores and low STAI-T scores reported the highest levels of Internet addiction. As the IAT does not specifically

measure how time is spent on the Internet, it is difficult to determine if the participants with high AQ scores and high anxiety were pursuing special interests, engaging in social media, or playing VVGs. In other words, some of the aforementioned activities may have a soothing effect while others may serve to escalate anxiety.

Mazurek et al. (2012) completed a study based on data from the National Longitudinal Transition Study-2 (NLTS-2). The vast majority of adolescents with ASD (64.2%) spent the bulk of their free time consuming television and video games. When video games and television viewing were separated, 41.4% spent the greater part of their free time consuming video games. When compared to adolescents with other disabilities, teens with ASD spent more time playing video games, and these differences reached the level of statistical significance. The amount of consumption created considerable interference with their activities of daily living and functioning. Only 28% of neurotypical teens qualify as high consumers of video games compared to 60.3% of adolescents with ASD. The greatest predictors of high use for teens with ASD included a higher IQ and access to technology in their homes.

Game Genres

In 2014, half of the ten top-selling video games were classified as VVG (Kain 2015). These include first-person-shooter games (FPSG) and role-playing games (RPG). First-person-shooter games (FPSG) allow gamers to immerse themselves into a three-dimensional world with the console screen serving as their means of experiencing the action from the point of view of the shooter (Schneider 2004). Contrary to popular belief, FPSGs are not always played in isolation. A study by Jansz and Tanis (2007) found that the majority of gamers who played FPSGs (80%) joined a clan, which allowed them to collaborate and compete with gamers at similar skill levels. This suggests there is a social motive to the play of neurotypical gamers, though it is unclear if people with ASD play FPSG in the same way or for the same purposes. Barlett et al. (2007) found significant increases in levels of aggression in participants after playing

FPSGs for a mere 15 min. They propose that priming for aggression occurs when a person is exposed to VVG which triggers aggressive thoughts and ultimately aggressive actions. This high level of primed aggression is exacerbated by the amount of blood and gore that accompany an aggressive action within the game.

Role-playing games (RPGs) differ from FPSGs in that they allow the person with ASD to immerse themselves in the game by taking on an avatar within a fantasy world, setting out on quests, and exploring against the backdrop of a story line or dialogue. Gamers who engage with RPGs tend to play longer (23–25 h a week versus 16 h per week for FPS gamers) (Ng and Wiemer-Hastings 2005; Jansz and Tanis 2007) and develop substantial attachments to their character (Lewis et al. 2008). These character attachments are formed as the gamer's actions shape the development of the story line, and the gamer becomes more immersed and integrated with his/her avatar. In their study on character attachment, Lewis et al. (2008) found that gamers with stronger character attachments were motivated by fantasy seeking, social interaction, and diversion. This raises a question regarding the degree to which a gamer with ASD would form attachments with a character in an RPG (Kowert and Oldmeadow 2014). Does a competent avatar allow a person with ASD to feel more competent and less socially anxious? Does the avatar become the surrogate friend in the absence of real-world friendships, thus limiting real-world social experiences and exacerbating social impairments?

Mazurek and Engelhardt (2013) examined the relationship between video game play and scores on measures of problem behavior in a sample of 169 boys with a diagnosis of ASD. Video games were identified as fitting into the category of RPG or FPSG. In this study, the amount of video game consumption did not demonstrate an association with maladaptive behaviors. However, there was a statistically significant positive relationship between type of game (RPGs) and scores on measures of oppositional behavior. There was also a positive relationship, though not reaching the level of statistical significance, between FPSGs and oppositional

behaviors. Additionally, there was a statistically significant positive relationship between FPSGs and addictive gaming behaviors.

Chung et al. (2015) examined the effects of active video game play (AVG) on the social behaviors of children with ASD. In this single-subject design study, children with ASD played with their siblings with measures taken on joint positive affect, reciprocal conversation, and aggression. Primary analysis suggested that AVGs have an inconsistent effect on the socialization of children with ASD and their siblings. Of particular interest, however, was a finding in the supplementary analysis of the augmented reality (AR) condition. The AR was originally conceived to provide a bridge between sedentary and active game play and to introduce the more cooperative style of play with the sibling. Rather than using an avatar, the AR condition used a silhouette or photo-realistic image of the gamer. The AR condition was statistically significantly more preferred by the majority of participants with ASD, and they reported a more positive experience with the AR condition.

Social learning theory (Bandura and Walters 1977; Bandura 1997) has demonstrated the impact of modeling on children's acquisition of social, emotional, behavioral, and functional skills. According to Bandura's social learning theory, children pay particular attention to models who share their salient demographic characteristics and models perceived to be competent. These models can continue to influence the child beyond the context of the original observation and do not require reinforcement for behavioral modeling to occur. Social learning theory may explain why the AR conditions in the Chung et al. (2015) study were preferable to the children with ASD. It may also begin to explain the underlying mechanism for VVGs as potential video models of aberrant behavior in adolescents with ASD.

Violent Video Games as Video Models

Ferguson and Kilburn (2010) have raised the issue of selection to explain the relationship between VVG play and aggression. It is possible that people who are naturally more aggressive play more violent video games. Przybylski et al. (2009)

found that while the level of violence in a video game did not enhance enjoyment, those with higher scores on measures of trait aggression strongly preferred VVGs over NVG, and this was strongly predictive of their future choices of VVGs. Alternately, violent video games may result in increases in aggressive behavior. There is ample research that supports the finding that observation of violence in the home, community, and school is detrimental to children and increases their risk of engaging in violent behavior (Cummings et al. 2010; Henrich and Shahar 2013). Bushman and Huesmann (2013) support the position that there is an interaction between aggression-prone personalities and social cognitive learning, including observational learning. Randomized, controlled studies have demonstrated that decreasing access to media violence and teaching children rules against mimicking violence they see have both shown a decrease in aggression (Moller et al. 2012).

Video modeling is an evidence-based strategy utilized to teach pro-social behaviors to people with ASD that capitalizes on the strong visual learning skills of this population. Point-of-view modeling enables the person with ASD to see what the behavior looks like from the standpoint of the person engaging in the target behavior. These pro-social behaviors can include ending a conversation appropriately, asking for help, or entering into an ongoing conversation (Bellini and Akullian 2007). Video modeling allows for the repeated and consistent use of models that do not vary from time to time as they would likely do with a live model and has been successful in teaching and maintaining imitation skills in children with ASD (Cardon and Wilcox 2011). Video modeling is an effective tool for teaching pro-social behaviors, though it is not clear to what extent VVGs are impacting aberrant behavior by providing antisocial models for adolescents with ASD. Strong visual skills, circumscribed interests, difficulties in syllogistic reasoning, deficits in ToM, and problematic/addictive gaming behaviors may serve as a confluence of vulnerabilities rendering the adolescent with ASD vulnerable to emulating the behaviors viewed during hours of VVG playing.

Future Directions

Future research should consider the factors that may be contributing to mass shootings perpetrated by young men with ASD and comorbid psychiatric disorders who spend significant amounts of time playing VVGs. Does their propensity toward visual learning make them more vulnerable to violent images? Are deficits in perspective taking that make it difficult for them to consider how their behavior impacts others, being exacerbated by the dehumanization of victims within video games? Is this violent modeling generalizing to real-life behaviors? Are some people with ASD more impacted by violent images than others and if so, what variables moderate that impact? Are the feelings of empowerment provided by video games serving to galvanize aberrant behavior?

It is incumbent upon the ASD community, including people with ASD, advocates, families, and professionals, to demonstrate an understanding of the impact of violence consumption on people with ASD through the development of reasonable game play guidelines. Components of VVGs that may make them appealing to the player (pace, level of competitiveness, graphics, frequency of rewards) could be identified, and alternative games could be substituted that would still allow the person with ASD access to an equivalent gaming experience without subjecting them to graphic violence. This may serve as a mechanism for families to provide acceptable gaming alternatives thus avoiding the resultant problem behaviors that come with placing restrictions on their video game play.

While these questions are being investigated, we must consider the amount and type of violence adolescents with ASD are routinely consuming and work toward developing nonviolent alternative interests both within and outside of the digital world.

Definition

Video games are electronic media with three key attributes: they display content visually, they are interactive, and they are typically used for entertainment or have entertainment-like qualities. Video games encompass a wide array of formats, applications, and designs, ranging from simple hand-held gaming devices depicting black and white rasterized characters, to fully immersive virtual reality simulators.

In general, video games are separate from electronic screen media, because electronic screen

media do not necessarily require an interactive component. Video games are separate from computer-assisted instruction and computer-based intervention, as video games are typically associated with entertainment, and computer-assisted instruction and computer-based intervention involve a therapeutic or didactic element or intention. Similarly, a distinction can be drawn between software, in general, and video games (which can be a specific type of software), as the goal in most software is typically to facilitate an external goal in the most efficient way possible (e.g., summing numbers, looking up information on the internet, or reading an Encyclopedia of Autism entry); the goal for video games typically lies within the game itself or is defined by the game (e.g., to “win” the game, to solve a puzzle, or to “beat” another player).

It is important to note that the line between video games and other forms of interactive electronic media is somewhat indistinct. It could be argued that some computer-based interventions are, in fact, video games, since they rely on games (in particular, other video games) as a basis for design (e.g., the Memory game, played with emotional faces, for individuals with autism). Nevertheless, the term “video game” is sometimes avoided by researchers who wish to highlight the advantages and potential of this media format while avoiding the perceived negative connotations associated with, for example, video game violence or obsessive video game play that serves no positive remedial goal.

Historical Background

History of Video Games

One of the first reports of video games was filed in a patent, “Cathode-ray tube amusement device,” in 1947 by Goldsmith and Ray (1948; Mitra 2010). This patent described a game system in which a cathode-ray tube was used as the face of the console, displaying a single moving point, representing a missile fired toward drawn figures overlaid upon the tube. Over the next two decades, other video games slowly emerged, driven by advancements in computer technologies and increasing sophistication with computer

programming. Notable games during this time included “OXO,” a tic-tac-toe program written as part of a University of Cambridge Ph.D. dissertation, by Alexander Douglas in 1952; “Tennis for Two,” a tennis game played on an oscilloscope screen at Brookhaven Nation Labs, by William Higinbotham in 1958; and “Spacewar!,” a two-player vector-based space combat game designed to showcase the Digital Equipment Corporation’s recently developed computer, the PDP-1, by MIT students Steve Russell and others in 1962 (Burnham 2001; Donovan 2010).

Through the 1960s, video games were primarily viewed as sophisticated but impractical novelties, due to their size and expense. However, as the cost and size of electronics and microprocessors began to rapidly decrease, video games became more viable as a form of entertainment. In the 1970s, beginning with the successes of coin-operated arcade systems such as Pong, video games came into vogue and quickly became significant segments of the entertainment market (Donovan 2010). The late 1970s saw commercial successes by companies such as Atari, and by the early 1980s video games had moved into the home in the form of consoles and personal computers, ushering in the modern era where video games have never diminished from public consciousness (Donovan 2010; Kent 2001).

Video games have continued to innovate and redefine themselves (Donovan 2010). In the early 2000s, internet games became popular, allowing players to participate in games with tens or thousands of other players at the same time. Simultaneously, mobile devices like cell phones began to allow gaming on devices that were cheap and portable and therefore ubiquitous. Today, this interconnectivity and ubiquity of access define some of the most modern aspects, and modern challenges, of video game technology.

Types of Video Games

The taxonomy of video games is a complex subject (e.g., see Apperley 2006; Wolf 2002). However, one useful classification scheme involves the discussion of video game “genres.” A review by

Yuan et al. (2010) identifies the following (non-exhaustive and non-mutually exclusive) categories of games: (1) first-person shooter, (2) strategy games, (3) sports games, (4) role-playing games, (5) puzzle games, (6) racing games, (7) dance/rhythm games, and (8) adventure games.

Another distinction in video games is between “serious video games” versus “non-serious video games.” Serious video games represent games intended to fulfill a role other than (or in addition to) pure entertainment, with the typical assumption that they will foster some specific skill acquisition or broader learning (Rego et al. 2010; Susi et al. 2007). Others, however, argue that such a distinction is artificial, and that even games not originally intended to be “serious” can be used for serious intentions, such as education (Breuer and Bente 2010; Squire 2003).

The Demographics of Video Games and Video Game Players

Today, video games collectively represent a more than \$67-billion-a-year industry globally, putting the industry on equal footing with the music and film industries (Gartner 2011). In the USA, video game platforms are popular and widespread. Consumer spending for the video game industry in the USA in 2010 was \$25 billion, with 72% of households playing (Entertainment Software Association 2011).

More males than females play video games, but recent estimates by the Entertainment Software Association (2011) suggest that a sizeable 42% of game players are women and that females aged 18 and older are a group of game players three times larger than males 17 years of age and younger. Despite this, it is well known that women, along with minorities, are underrepresented as characters in video games (Terlecki et al. 2010; Williams et al. 2009). Furthermore, research has found that the representation of women in video games is often sexually stereotyped, potentially contributing to feelings of inadequacy and the internalization of stereotypes, especially by young females (Dietz 1998; Dill and Thill 2007).

Positive and Negative Effects of Video Games

Video games can have both positive and negative qualities (Kirriemuir and McFarlane 2004; Lee and Peng 2006; Mitchell and Savill-Smith 2004) and, as with other forms of media, video games have had their share of controversy. One of the first video games to generate bad publicity for the fledgling industry was the video game *Death Race* (Exidy 1976), a game where players controlled a car and received points for driving over people (Donovan 2010). This began a long disagreement over the role of violence in video games in potentially encouraging or exacerbating aggressive or violent tendencies, a disagreement that continues to this day (Mitchell and Savill-Smith 2004). While some meta-analytical research suggests that violent video game play is causally linked to increases in real-world aggression and decreases in prosocial behavior (Anderson and Bushman 2001; Craig 2004), other researchers challenge these assertions (Ferguson 2007, 2010). Some argue that violent video games might be a cathartic experience for players, allowing players to release pent-up aggression, anxieties, and energy, though evidence to this effect is scant (Lee and Peng 2006).

Similarly, the widespread popularity of video games and internet video games, in particular, has resulted in increasing focus on the phenomenon of video game addiction (Young 1998). A recent review of internet gaming addiction (Kuss and Griffiths 2011) suggests that individuals with video game addictions share similarities with individuals with other forms of addiction in terms of neural activation patterns (e.g., see Ko et al. 2009), atypical personality traits (e.g., bipolar disorder and depression; see Shapira et al. 2000; Young and Rogers 1998), and poor maintenance of real-world social relationships (Allison 2006). Yet, Kuss and Griffiths (2011) point out that gaming addiction exists on a spectrum of severity, where most video game players do not exhibit concerning levels of video game play.

The flip side to video game addiction is that the games are designed, of course, to be as fun as possible. While addictions that interfere with daily living are certainly an unfortunate consequence, they can be seen as the natural extension

of the continuum of the qualities that make certain games popular, namely, their addictive nature. What makes one game more playable and replayable than another has been a constant question for video game designers (Salen and Zimmerman 2004). One useful perspective involves the concept of “flow” (Csikszentmihalyi 1991). Flow is a state in which a person operates at his or her peak ability, with focused motivation and full involvement dedicated to overcoming or completing a challenging task. The ability to evoke flow in its users has been described as an attribute of highly successful video games (Chen 2007), with play that walks a fine line between anxiety and boredom (Cowley et al. 2008). These flow states have been described as extremely meaningful, enjoyable, and illuminating experiences; the ability of video games to instill a flow state into players could, from this point of view, be described as a positive experience. For example, Bowman (1982; as discussed in Squire 2003) analyzed the Pac-Man video game in the context of flow, and identified qualities that promoted flow states during its gameplay: “skills and challenges are progressively balanced, goals are clear, feedback is immediate and unambiguous, and relevant stimuli can be differentiated from irrelevant stimuli.” Bowman suggested that educators should aim for these qualities to design learning environments that are engaging.

Yet, detractors of video games would be quick to point out that video game play involves consumption rather than creation, resulting in no tangible benefits to either the player or the world at large. Such arguments parallel historical arguments against other forms of media, such as television viewing, and there is a real concern that, to some extent, excessive video game play may be displacing other activities such as schoolwork. These concerns are supported by some studies, especially for violent games played by excessive video game players (Gentile and Gentile 2007; Harris and Williams 1985), but seem to be a lesser concern for the majority of video game players, who do not play excessively (Christopher 2011; Gentile and Stone 2005). For example, a study by Durkin and Barber (2002), which looked at 1,304 16-year-old high school students, found that video

game play was associated with positive attributes (e.g., positive mental health and friendship networks) rather than negative ones (poor school performance). A similar concern has been raised regarding the possibility that video game play may be displacing sports and other physical recreation (Kirriemuir and McFarlane 2004; Vandewater et al. 2004). On the other hand, the evolution of video game technologies has seen the advent of games that can place physical demands on players, for example, by requiring players to swing a paddle or to dance. Studies of these physical video games suggest that they can generate the same level of physical activity as light jogging or walking (Maddison et al. 2007).

It can be argued that video games are in and of themselves neither good nor bad, but rather it is in their use, abuse, and interpretation in which such distinctions are made. Video games, from one point of view, are just a particular form of game; games in turn, are a specific form of play. Developmental psychologists have long argued that play is important for children (e.g., Bruner et al. 1976; Piaget 1962; Vygotsky 1978), and modern views place games and play as developmentally critical to cognitive development, abstract thinking, self-identity, and social and cultural learning (Bornstein and O'Reilly 1993; Johnson et al. 2005; Pellegrini and Smith 1998). Similarly, the role of games in fostering or facilitating learning has been examined (Boocock and Schild 1968; DeVries and Edwards 1973; James 1966; though see Inbar and Stoll 1970). However, it is clear that the intentions of the designers of games are paramount. For example, educational video games are one set of games that seek to achieve positive goals for their users. Yet even within this domain, grounding the design of video games from perspectives of development and learning theory may be necessary in order to help designers achieve the most positive impact (Verenikina et al. 2003).

History of Educational Video Games and Edutainment

Though computers had been used for educational purposes before (see Suppes 1966), one of the earliest widely used educational video games, *Oregon Trail*, was created by Don Rawitsch, Bill Heinemann, and Paul Dillenberger in 1971 as a

demonstration for a history class that Rawitsch was teaching (Lussenhop 2011). This video game was an all-text adventure presented as an exercise in resource management (Perron and Wolf 2008). Later, while working for Minnesota Education Computing Consortium (Haugo 1973), Rawitsch expanded upon the educational aspects of the game, creating an early precursor of modern day video game “edutainment.”

The term “edutainment,” a combination of “education” and “entertainment,” represents programs that perform educational functions while providing the entertainment value of regular games (Okan 2003; Resnick 2004). Many of the most popular educational video games that followed *Oregon Trail*, such as *Reader Rabbit* (The Learning Company 1984) and *Math Blaster* (Eckert and Davidson 1987), were edutainment titles, structured in order to make drill-and-practice exercises more palatable to young children. Yet, this strategy has left some video game theorists and computer education experts wanting. For example, Mitchel Resnick criticizes modern edutainment software companies as being unnecessarily rigid in their views regarding learning and education, preferring instead a playful approach toward learning that focuses on intrinsic rather than extrinsic rewards (Resnick 2004). Similarly, Simon Egenfeldt-Nielsen noted that edutainment computer games are easily identified by reward structures that are completely disconnected from the educational aspects of the game (Egenfeldt-Nielsen 2007) and was likewise critical of their superficial perspectives on learning.

Superficial or not, educational video games gained great popularity in the 1980s, in part due to the increasing availability of computers in the classroom (Becker 1991) and in part due to the attractive notion of combining the “tedium of education” with the fun of games. Most studies examining whether video games could indeed foster learning showed positive results (for reviews, see Egenfeldt-Nielsen 2006; Kirriemuir and McFarlane 2004; Mitchell and Savill-Smith 2004; Squire 2003). For example, Din and Calao (2001) showed that children playing educational video games designed for kindergarten students improved their ability to spell and decode words when compared to control children; similarly,

Thomas et al. (1997) showed that an adventure video game designed to teach safe-sex skills to high-risk adolescents was effective in improving knowledge as well as perceptions of self-efficacy. Critics of the educational video game literature, however, argue that proof of learning is only the first bar to be hurdled in proving video games a useful tool in the classroom experience (Egenfeldt-Nielsen 2006, 2007), and that a more appropriate comparison is to show that video games provide additional gains in comparison to more standard forms of teaching.

Like video games in general, educational video games continue to evolve. Egenfeldt-Nielsen (2007) describes a model where three generations of video games in education correspond to the broader evolution of psychological and educational perspectives and beliefs. Egenfeldt-Nielsen notes that the first generation can be defined by a behaviorist viewpoint that sees drill-and-practice in the context of extrinsic reward (i.e., most edutainment titles) as a sufficient route by which to inculcate learning. The second generation is defined by a cognitive approach, a view that sees intrinsic motivation and internal mental states as central to learning (e.g., games which encourage a discovery process such as *Super Tangrams*; see Sedighian and Klawe 1996). Between the second and third generations, there is a constructionist perspective, which is similar to the cognitive approach, but emphasizes the role of tangible objects and experience, as exemplified by “micro-world” simulation video games, such as *SimCity* (Games and Squire 2011). The third generation, according to Egenfeldt-Nielsen, is the sociocultural approach, one which sees educational video games themselves as only one piece of the educational puzzle, with a broader context that includes teachers, other students, and the transformation of knowledge through exploration, examination, play, and discourse.

Current Knowledge

Recreational Use of Video Games in Individuals with ASD

Video games have many qualities that make them attractive to some individuals with ASD. An early

assessment of computers in use with autism listed three reasons why computers are attractive to children with autism: computers are nonsocial, they are consistent and predictable, and the child can control and determine the pace of an experience (Swettenham 1996). Other aspects of video interfaces that appeal to individuals with ASD differ from the attractions for typically developed individuals. For example, Mineo et al. (2009) studied the use of multiple forms of electronic-screen media among students with ASD and discussed the attraction of electronic-screen media for individuals with ASD in the context of qualities, such as the de-emphasis on language skills, the constrained viewing area requiring limited attention, its visual modality, and the ability to repeat experiences over and over. Also, Durkin (2010) has noted that the sensory experience of children with autism may be different than typically developing individuals (see also Simmons et al. 2009), and that they appear to have superior performance on some visual tasks but not others.

The absorbing, repetitive, and rewarding nature of computers and computer games has the potential to harm or help individuals with ASD. In the home, nontherapeutic games might encourage social disengagement by displacing social interaction, as is seen in excessive video game players who are otherwise typically developing. Anecdotal reports on ASD video game use and social disengagement are not uncommon, and have been supported by survey data. A study in Mazurek et al. 2011 by Mazurek, Shattuck, Wagner, and Cooper found that 41% of youths with ASD spend most of their free time playing video games, a higher percentage than for other developmentally disabled youths, and higher in comparison to the 18% of youths in the general population who are considered to be high users of video games. Compared to adolescents with typical development, adolescents with Asperger syndrome are less likely to use cell phones for social communication and more likely to use them for non-communicative activities, like games (Durkin et al. 2010). Interestingly, a survey of 23 youths with Asperger syndrome found that several of them listed video games as an apparent special interest. But interviews revealed that the youths often used video games and other more socially

acceptable interests to mask separate special interests that were perceived to be less socially acceptable (Winter-Messiers 2007). These individuals often used video games as a social bridge to help them interact with typical individuals.

Therapeutic Use of Video Games in Individuals with ASD

Computer games have shown the potential to cause brain function changes in typically developed individuals. In particular, action video games have been shown to induce a broad class of changes such as contrast sensitivity, spatial resolution, visual attention, and visuomotor coordination (Spence and Feng 2010). However, others have pointed out methodological shortcomings in studies showing benefits of action video games (Boot et al. 2011). Computers have also been used to target brain training in subgroups of typical individuals. In infants, computers have been used to train visual attention (Wass et al. 2011). In the elderly, cognitive training has been used to attempt to maintain or improve cognitive abilities (Schmiedek et al. 2010), although another study showed a failure of such training to generalize to closely related untrained tasks (Owen et al. 2010).

Because of the increased attraction for computers, video games, and other electronic screen media shown by many individuals with ASD, some educators have suggested that video games (educational or otherwise) might be an effective tool in the therapy and education of individuals with ASD (see ► [“Computer-Based Intervention Assistive Technology”](#) specifically, but also ► [“Video Modeling/Video Self-Modeling”](#) and ► [“Video Instruction”](#)). Whereas computer-assisted instruction (CAI) has been used to understand and treat deficits associated with autism since the late 1960s and early 1970s (Colby 1968, 1973), the use of a video game approach (Chaffin et al. 1982) for therapeutic goals has been a relatively recent research focus. The distinction between computer-assisted instruction (CAI) and computer games is not easy to make. A natural approach is to assert that games involve “play,” and instruction does not. However, CAI often crosses the line into video games. For example,

the study of TeachTown, a CAI program, used animated games as rewards for correct responses (Whalen et al. 2010). Its reinforcers were designed by professional video game designers (Whalen et al. 2006), and the program has been described as a suite of “game-like tests” (Wilkinson et al. 2008).

Video games and CAI have been used in several studies to teach foundational social skills to teach children with ASD. The typical goals of such training are to teach kids to look at faces (Trepagnier et al. 2006), to identify emotions or faces (Beaumont and Sofronoff 2008; Tanaka et al. 2010), to express emotions (Cockburn et al. 2008), and to play collaboratively with other children (Battocchi et al. 2010; Gal et al. 2009). Though skill and knowledge acquisition are the main use of video games for individuals with ASD, games can also be used as rewards in conventional therapy, and as adjuncts to conventional therapy.

One class of computer games involve extending non-computer games into the computer realm. Gal et al. (2009) and Battocchi et al. (2010) are examples of computerized interventions that use tablet input to build on the ideas of collaborative play therapy, where two children must collaborate to accomplish goals on the tablet device. One potential advantage of such computerized therapies is that the computer can easily be tailored to special interests of individuals with ASD to increase interest and engagement. Such tailoring has been used for interventions using non-computer-based games (Baker 2000). Morris et al. (2010) describe successful use of such tailoring for a computer-based exposure therapy, in which an individual with ASD was at first uninterested in the computer therapy, but became deeply engaged by a specifically tailored version of the software that used images of his special interest: newborn babies. They created software that quickly produced background-free images from the internet that were tailored to any specific special interest. They then used this software to customize computer games to the specific special interests of nine individuals with an ASD diagnosis and showed that seven of them preferred to play the customized versions.

Several groups have used video games or video game concepts in larger studies of individuals with ASD (Hopkins et al. 2011; Tanaka et al. 2010; Whalen et al. 2010). Hopkins et al. (2011) developed a computer-based social skills training program called *FaceSay* and employed it in a 6-week randomized control study of 49 high-functioning and low-functioning children with ASD. The results of this study showed that *FaceSay* was useful in teaching emotion recognition skills to low-functioning children with ASD and improving their social interaction. High-functioning children in the study gained in these skills as well as in face recognition ability. Tanaka and others (2010), used a suite of video game-like programs designed to teach face processing skills to children with ASD (the *Let's Face It!* battery), and showed that after just 20 h of intervention using the programs, children in a treatment group ($N = 47$) showed improvements in critical face processing skills compared to controls ($N = 37$). Whalen et al. (2010) used a combined CAI/behavioral intervention approach called *Teach Town: Basics* in a 3-month intervention study using 40 min of activity per school day for 22 children with ASD, comparing to a control group that received regular school instruction ($N = 25$). Whalen found that the intervention group receiving *Teach Town: Basics* showed gains in receptive language and expressive vocabulary compared to the control group. These three studies provide evidence that video games may be an effective tool in providing services to individuals with ASD.

Concerns, Limitations, and Recommendations

There is good evidence that video games may provide a teaching format that helps individuals with ASD learn. However, as highlighted by Egenfeldt-Nielsen (2007), to show that learning is taking place through video games is only the first step in proving the efficacy of video game formats as a therapeutic aid; the careful choice of control conditions (e.g., comparably intense and well-designed non-video-game therapies) will be critical in identifying the advantages and disadvantages of video games in individuals with ASD.

In particular, it is important to note that research shows video game use, and more concerningly, excessive video game use, may be more prevalent in individuals with ASD than in individuals with other developmental issues. For very attractive and fun video games, there is a concern that over time, despite initial intentions, their use by individuals with ASD may become repetitive and more purely stimulatory, ceasing to provide social, communicative, and other educational gains. Furthermore, there is the possibility that skills mastered through CAI and educational video games may not translate or generalize to real-world situations. Though the promise of this technology is great, the dangers are also real, and care must be taken to monitor the utility and pitfalls of this technology. For this reason, it is recommended that video games used for treatment purposes in individuals with autism be part of a combined intervention, under the supervision of experienced clinicians.

Future Directions

Technology is advancing rapidly, and with these advances, the promise of video games and automatic instruction for individuals with ASD seems to grow larger daily. Today, tablet devices, like the iPad, use finger touch as the basis of a look-and-touch interface that is intuitive for young children and accessible to people with developmental disorders (Henderson and Yeow 2012). Console controllers like the Wii and the Kinect use input based on sensing body motion; the use of such body motion in games is highly intuitive and immersive and may provide a physical aspect to video games, with potential benefits to skill generalization. Simultaneously, internet accessibility is becoming ubiquitous, increasing the possibility that individuals with ASD may be able to develop social networks and foster social development through nontraditional means.

From the research point of view, future directions include more large and well-controlled studies of the efficacy of video games, including studies of generalizability of skill acquisition; more concerted efforts to understand the nature

of what makes video games appealing to certain individuals with ASD, and how to manage the potential for abuse; and a continuing focus on the educational role that video games may play for individuals with ASD, with particular attention toward how video games should be tailored to the characteristics of an individual on the spectrum.

Video Instruction

Definition

Video instruction is a teaching technique where learners perform specific target skills (e.g., social, communication, academic, daily chores, vocational, recreational) in natural activity contexts immediately after watching a customized video in which a model performs the expected target behaviors. The video model could be same-age peers, siblings, adults, or the learners themselves. Video instruction comprises several techniques including video modeling, video self-modeling, point-of-view video modeling, and video prompting.

Video modeling is described as a process where (1) a video clip is created that shows a model performing the target skill in a specific activity context in its entirety; (2) a learner is asked to watch the video clip prior to entering the same activity context; (3) an instructor provides prompts and reinforcers to the learner for attending to relevant stimuli; and (4) the learner imitates the observed behavior when provided with the opportunity to perform the same skill.

Video self-modeling is where learners themselves serve as a model by performing the desired target behavior. In this process (1) *only* the exemplary target behavior of the learner is recorded and displayed on the video minus instructor prompts and reinforcers; (2) the learner observes his/her own adaptive behavior in the video; (3) the learner is provided with opportunities to imitate his/her own target behavior in the activity context after watching the video; and (4) after repeated practice, the learner performs the desired target behavior.

Watching oneself performing the desired target behavior increases the learner's self-perception of competence (Mason et al. 2016).

Point-of-view video modeling has been defined as the process of videotaping elements of the physical environment or activity context from the *visual perspective or vantage point* of the learner who needs to acquire and/or master the desired target responses (Hine and Wolery 2006; Mason et al. 2013; Spencer et al. 2015). In this process:

1. The videographer keeps the camcorder at the eye level of the learner while sequentially recording the hands of a model completing the steps of an activity. If the video clip is to teach a transition routine, then only the physical settings are recorded.
2. The learner reviews the video clip and observes exactly how to navigate the task or routine from start to finish.
3. The learner performs the behaviors observed in the video clip.

Repeated review of such video clips is more likely to promote visual comprehension, increase familiarity with materials and settings, and provide a "picture" of the completed process, ostensibly reducing task anxiety and inappropriate behavior.

Whereas video modeling demonstrates an entire set of target behaviors in a sequential manner, **video prompting** breaks down a chain of tasks into individual clips, making it easier for learners to perform each step accurately before advancing to the next step in the activity chain (Sigafoos et al. 2007; Wu et al. 2016).

During **video feedback**, the target student and the instructor view the video clip recorded during a natural activity context. Based on the observed behaviors of the student, the instructor provides specific performance feedback including reinforcers for accurate responding and corrective feedback for incorrect responding. It is believed that the specific focus on the target behaviors increases the probability of correct responding in the future (Thiemann and Goldstein 2001).

Historical Background

The concept of modeling for observational learning dates as far back as 48 years to the social learning theory exemplified by Albert Bandura (Bandura 1969, 1976). This theory emphasized the importance of observing and modeling behaviors, attitudes, and emotional reactions of others. This theory explained human behavior in terms of continuous reciprocal interaction between cognitive, behavioral, and environmental influences (Bandura 1969, 1976). Bandura's early work focused primarily on neurotypical individuals and those with psychological disorders utilizing the behavior modification framework.

Inspired by Bandura's work on observational learning, Creer and Miklich (1970), as cited in Dowrick (1999), asked a young boy who had asthma and behavior problems to role-play adaptive behavior. Authors reported that the role-play per se did not make a difference but watching himself on the video improved the boy's behavior. Creer and Miklich then coined the phrase "self-modeling" to describe this process (Dowrick 1999). During the 1970s, also inspired by observational learning, Hosford and his colleagues had started to use "self-as-a-model" in behavioral counseling sessions with adults on the assumption that a similarity between the model and observer contributed to positive effects (as cited in Dowrick 1999). Based on these reports and his own work on self-efficacy, Bandura advocated for the use of film as a teaching tool in 1976 to enable children to perform desired behaviors after watching themselves acting appropriately.

Video instruction has evolved since the 1970s as an intervention strategy of choice. Its effectiveness has been documented in the literature with regard to training with a variety of populations (e.g., children and adults with and without a disability) on a variety of skills including athletics, academic tasks, social interaction, and functional life skills.

Previous and current research reviews have indicated the effectiveness of video instruction for learners with an autism spectrum disorder on a variety of target skills including social-communication (Green et al. 2017; Lee et al.

2017; Macpherson et al. 2015; Shukla-Mehta et al. 2010), daily living (Mechling et al. 2015), academic (Yakubova et al. 2016), vocational (Seaman and Cannella-Malone 2016), and recreational skills (Sherrow et al. 2016).

While several previous studies reported the use of video modeling as the only intervention component (MacDonald et al. 2005; Nikopoulos and Keenan 2007), recent research and reviews have focused on evaluating the parameters of video instruction packages through comparison studies (Bennett et al. 2017; Mason et al. 2016).

Rationale or Underlying Theory

Autism spectrum disorder is classified as a neurodevelopmental disorder that significantly affects social interaction, verbal and nonverbal communication, interests, activities, and behavior across the lifespan. Awareness and acknowledgment of these skill deficits reiterates the need for using evidence-based practices for learners with ASD across the lifespan. Recent research reviews have presented several compelling reasons for continuing the use of video instruction for learners with ASD to increase a variety of skills (Bennett et al. 2017; Mason et al. 2016; Shukla-Mehta et al. 2010).

Positive outcomes have been documented for learners with ASD when video instruction compared to other methods was used to teach social interaction (Malmberg et al. 2015; McDowell et al. 2015) and gaming skills (Spriggs et al. 2016). With repeated practice and feedback, such skills are more likely to generalize to natural environments (Jones et al. 2014; Smith et al. 2016). Additionally, because video clips can be easily accessed, opportunities to repeatedly watch video clips may result in mastery of skills in a relatively shorter period of time.

Video instruction utilizes systematic instruction; thus, learners are more likely to discriminate between accurate and inaccurate responses. Also, receiving visual and verbal feedback on one's own behavior is often more effective than receiving skills instruction alone. Performance feedback provides concrete information to learners with

ASD and promotes comprehension regarding the accuracy of their response. Video instruction is more likely to deliver focused and systematic visual and verbal feedback when compared to live instruction (Spriggs et al. 2016).

The fact that video clips can be accessed across multiple platforms of mobile devices makes this teaching method not only effective and efficient (Bennett et al. 2017; Mason et al. 2016) but also age and culture appropriate (Odom et al. 2015; Rajendran 2013). Additionally, it facilitates the ultimate goal of independent functioning in adolescents and adults (Ayres et al. 2013; Seaman and Cannella-Malone 2016).

Goals and Objectives

The purpose of video instruction is to allow learners to observe the appropriate actions for performing the target behavior immediately prior to performing the response or skills in the natural environment, increasing the probability of successful performance. Specifically, video instruction is designed to increase a variety of target skills including social-communication, daily living, academic, vocational, and recreational skills. The additional purpose of video instruction is to decrease the problem behavior of individuals (Green et al. 2017).

Treatment Participants

Video instruction has been found to be effective across all age groups of neurotypical and neurodiverse individuals including those with ASD, ADHD, emotional and behavioral disorder (EBD), developmental disability, and language and communication disorder; however, a vast majority of the studies have involved learners with ASD. Learners are more likely to benefit from video instruction if they have skills in (1) attending to relevant stimuli (e.g., cues and prompts in the video); (2) imitating physical and social behavior of the model; (3) visual processing and comprehension of the video content; (4) matching-to-sample and spatial ability to

generalize the target behaviors in real activity settings after having observed the video; and (5) attending to a video clip of at least 1 min in length.

Treatment Procedures

The key procedures of implementing video instruction include both preparing the learning environment and delivering the instructional procedures. Based on previous and current reviews of research on video instruction, the use of systematic instructional procedures based on the principles of behavior is very effective for skills instruction for learners with ASD (Bennett et al. 2017; Mason et al. 2016; Odom et al. 2015; Shukla-Mehta et al. 2010). The step-by-step procedures are as follows:

1. Identify or pinpoint the target responses that need to be increased or decreased and operationally define or describe these behaviors. Develop a unit of measurement to measure the behavior.
2. Identify the setting or activity context in which the target behavior needs to be changed.
3. Identify the model (e.g., adult, peer, sibling, or learner himself/herself) who will display the appropriate behavior and participate in the video production. In existing research, the type of model (i.e., peer, self, or adult) did not appear to affect learning of the target responses in any significant manner.
4. Develop a script or list of actions that the model and other participants (e.g., teacher, peer, or parent) will use for the video demonstration. Role-play or practice the “scene” that needs to be recorded whether it is transition from one environment to another or a complex social interaction sequence. If the model is the learner with ASD, then it may be important to keep a recording device available at all times to capture the target behavior when it is displayed.
5. Plan for the type of video instruction method to use (i.e., video modeling, video self-modeling, point-of-view modeling, etc.) in order to adjust the distance and area of focus for creating the video clip.
6. Prepare the instructional context where the video clip needs to be recorded prior to creating the instructional video. For discrete behaviors of short durations, a 3–5-minute video clip is generally considered to be adequate. Plan on when, where, and how frequently should the learner watch the video. For children who were reinforced by watching videos, repeated viewing (3–4 times) has been known to be effective.
7. Let the learner watch the video clip immediately prior to the natural activity context in which the target skill needs to be displayed. During the viewing, the teacher might use prompts to direct the learner’s attention to the relevant environmental cues and to the model’s appropriate behavior. If the concept is complex (e.g., perspective taking), the teacher may pause the video to ask questions to ensure the learner’s comprehension. The correct response may be reinforced, whereas an incorrect response may lead to reviewing the video clip until a correct response is emitted. If video feedback is an integral component of video instruction, then the instructor and learner can watch the recorded performance to provide constructive feedback.
8. Provide the learner an opportunity to display the observed behavior in the natural activity context. Accurate display of the target behavior may result in natural reinforcers (e.g., a compliment or smile from a peer, task completion).
9. Teach the learner to use the technological device when using video self-modeling or video prompting for self-instruction purposes.
10. Whether video instruction occurs in the context of research or clinical activity, it is recommended that instructors take baseline, intervention, maintenance, and generalization data to demonstrate the effectiveness of this teaching method.

Efficacy Information

Based on recent research reviews exclusively on video instruction for individuals with ASD, sufficient evidence exists to support it as an evidence-based practice for teaching a variety of skills (Bennett et al. 2017; Mason et al. 2016; Shukla-Mehta et al. 2010). While research reviews have also been conducted by Odom et al. (2015) and Seaman and Cannella-Malone (2016), they involve the use of various types of technological interventions for adolescents and adults including but not exclusively video modeling.

Bennett et al. (2017) reviewed 24 studies involving a total of 89 participants (3–22 years) who were diagnosed with ASD and intellectual disability (ID) or other comorbid diagnoses. Their primary purpose was to compare different intervention components to determine which ones were the most effective in producing desired outcomes (e.g., type of model; narration versus no narration; screen sizes; video perspective; custom versus commercial videos; simultaneous VM versus video priming or delayed VM; combined comparisons; and miscellaneous studies where a comparison was between two or more teaching techniques). Results showed no differential outcomes across any of the components that largely favored one over the others. The only exception was where function-based vs. nonfunctional videos were more effective for participants. Because this review included a wide variety of target skills, the outcomes do not associate specific components with specific target skills.

In a meta-analysis of the effectiveness of video self-modeling (VSM), Mason et al. (2016) reviewed 14 studies that met the quality standards established by What Works Clearinghouse (Kratochwill et al. 2010). The review included 50 participants ranging from pre-kindergarten to post-secondary settings across a variety of disability categories including ASD (62%), ID (14%), EBD (18%), and learning disability (LD; 8%). Overall results on the effectiveness of VSM (used alone or with other components) indicated a moderate magnitude of change as a function of intervention. Thus, authors conducted additional analyses to identify potential moderators (p. 632).

In general, VSM was found to be more effective for learners with ASD and EBD, specifically involving positive self-review as opposed to editing video to only include target behavior. Additionally, VSM alone was more effective as opposed to combining it with other intervention components to both change specific target behaviors.

The review of research by Shukla-Mehta et al. (2010) included 40 studies with a total of 126 participants (2.5 to 20 years) where video instruction was used to increase social-communication skills of learners with ASD. Results showed that 23 of 30 (77%) VM studies reported clear acquisition of target responses for all participants with or without other instructional components. Of the seven studies that utilized VSM, only three reported effectiveness in teaching social and communication responses. Similarly, only three studies have utilized point-of-view modeling and all reported to improve target behaviors. Since then many studies have utilized various types of video instruction methods for teaching a variety of target skills. In a study that compared VSM with and without peer training, Bellini et al. (2016) showed that VSM alone increased unprompted social engagement for all three participants. The addition of peer training did not lead to changes in social engagement when compared to the VSM-only phase.

Overall, while various methods of video instruction have been documented to be effective, future research needs to focus on isolating specific VM methods by disability category and level of functioning while controlling for methodological rigor.

Outcome Measurement

The outcomes of video instruction have been measured mostly based on directly observable discrete target responses of participants. Additionally, outcomes were measured in terms of skill acquisition, maintenance, or generalization in the natural activity contexts. In addition to objective measures for assessing behavior change, outcomes assessment can also include social

validation. Social validity is central to the belief that video instruction will be used more frequently in applied settings by practitioners and parents if it is shown to be successful in increasing social and functional skills of learners with ASD.

Qualifications of Treatment Providers

Interventionists or treatment providers who are well versed in the use of systematic instruction procedures including modeling, prompting, corrective feedback, and contingent reinforcement are more likely to be successful in implementing video instruction with individuals with ASD. However, recent research (Allen et al. 2015) showed that parents can effectively use video instruction to increase functional life skills of an adolescent with ASD and ID.

Video Modeling/Video Self-Modeling

Patricia Prelock

Communication Sciences and Disorders, Dean's Office, College of Nursing and Health Sciences, Burlington, VT, USA

Definition

Video modeling is the use of video to instruct an individual on desired skills or behaviors by viewing someone demonstrating those skills or behaviors. The video model can take several forms including watching an adult, peer, oneself (also known as video self-modeling), or an animation. This instructional approach is designed to teach new or improve existing skills or behaviors. Video modeling is also used to replace or eliminate challenging or nonproductive behaviors. All behavior viewed on a video model is positive modeling of what should be done versus what should not be done. Inappropriate behaviors or observed errors are removed from the videos. Video modeling helps focus an individual's attention on the most relevant behaviors in the video so that with practice and rehearsal the individual learns and demonstrates the targeted behavior modeled (Prelock 2006; Prelock et al. 2011). Video modeling helps an individual translate and generalize what they learned in a video-modeling session to skill

acquisition in many aspects of daily life (Charlop-Christy et al. 2000; Shipley-Benamou et al. 2002).

Historical Background

Bandura's (1969) early work on social learning theory and the power of modeling to support learning as well as Dowrick & Dove, (1980) research on video modeling, including video self-modeling, provides the underlying historical framework for using video models and video self-models to increase positive behaviors. In fact, in the early 1970s, video self-modeling was used as an intervention strategy to support the learning and behavior of individuals with developmental disabilities. With the ongoing work of Marjorie Charlop-Christy, Scott Bellini, and Tom Buggey, interest in video modeling and video self-modeling as viable intervention strategies for children with ASD has grown. Positive outcomes have been reported for increasing play behavior, greetings, answering and asking questions, conversation language, and perspective taking and self-help skills, to name a few. With rapid expansion of and increased access to video-editing software, the use of video modeling and video self-modeling is likely to see a dramatic increase.

Rationale or Underlying Theory

Video modeling is grounded in social learning theory (Bandura 1969) and the influence of models on observational learning. Bandura (1969, 1977) describes two underlying theoretical considerations that support the use of video modeling and, in particular, video self-modeling. He found that the most effective models were those who shared attributes (e.g., gender, age, race, ability – those slightly more advanced than the observer) with the observer. He also described self-efficacy or how confident one feels about carrying out a task as critical to learning success. Video self-modeling is built on both of these theoretical foundations in that individuals observe themselves carrying out tasks with success.

Since it is often difficult for individuals with autism to focus their attention, the use of video that highlights relevant stimuli facilitates an individual's attention on what is most important for learning to occur (Prelock 2006). Video is also less socially threatening, does not require immediate responses, allows for repeated viewings, and focuses on the visual strengths frequently reported for children with ASD (Grandin 2006). Further, video self-modeling might affect memory. Kehle et al. (2002) propose that children viewing themselves performing positive behaviors might supplant their memories of inappropriate behaviors. Additional research is needed to more carefully examine each of these perspectives as an explanation of why video modeling and video self-modeling appear to lead to behavior change.

Goals and Objectives

Several goals have been addressed using video modeling. Much of the research has focused on facilitating social skills including emotion recognition (Golan and Baron-Cohen 2006); time engaged during play (Bellini et al. 2007); conversational speech, spontaneous greetings, labeling emotions, and perspective taking (Charlop and Milstein 1989; Charlop-Christy et al. 2000; Charlop-Christy and Daneshvar 2003; LeBlanc et al. 2003); and other social language skills (Buggey 2005; Maione and Mirenda 2006; Scattone 2008). Some recent efforts have investigated the use of video modeling to support academic tasks (Delano 2007). Communication goals that might be a focus for video modeling or video self-modeling include naming, responding to questions, asking questions, participating in reciprocal conversation, and improving prosody and intonation (Prelock 2006).

Treatment Participants

Video modeling appears to be an appropriate intervention across a range of developmental levels and ages. For children with ASD, the reported research focuses on children 3–15 years

of age, although some researchers describe using video modeling with preschool children through older adults. Video modeling has been applied to children across the autism spectrum with varying cognitive and linguistic abilities (Buggey 2005, 2012; Delano 2007; Sansosti and Powell-Smith 2008; Scattone 2008). Some evidence suggests that individuals with both severe autism and cognitive impairment may not benefit from video modeling, yet several researchers have reported positive outcomes for children with moderate to severe autism (Bellini et al. 2007; Buggey et al. 1999; LeBlanc et al. 2003).

Treatment Procedures

There are several steps to consider in the implementation of video modeling. First, a decision needs to be made about the behavior to be targeted. This should be a team decision, and the targeted behavior should be operationally defined so that it can be observed, measured, and is specific to the individual with ASD (Charlop-Christy 2004; Prelock et al. 2011). A task analysis is completed next so that the individual steps for the video model can be itemized. This should be guided by observations of individuals who are typically developing, and input should be gathered from those who know the individual best (e.g., parents, teachers). It is important to incorporate a motivating theme in what is being modeled based on the particular interest of the child or individual with ASD.

Actors for video modeling can be familiar or unfamiliar adults or peers who are able to follow a script that has been outlined by the team. The actors for video self-modeling would include the individual with ASD performing a task that is slightly beyond his/her current observed ability. Notably, there are two types of video self-modeling, *feedforward* and *positive self-review*. In feedforward, an individual is shown a video of himself/herself performing a new, developmentally appropriate behavior that the team hopes will facilitate forward movement in performing that behavior. Positive self-review includes the individual with autism performing a task he/she

already knows how to do, so performance success can be reinforced, maintained, and generalized.

When preparing the video, actors should speak slowly and clearly, and target behaviors should be clearly observable and exaggerated when appropriate. The actors' facial expression should be shown. There should be minimal distracters in the video so the individual can focus on the most relevant cues. When viewing the video, attention can be prompted by pointing and saying "watch" or "look."

Following the video viewing, it is important to debrief with the individual, reviewing what was seen and heard, identifying the targeted language, noting the prosody and emotional expression of the models, and talking about variations in the scenarios (Charlop and Milstein 1989; Prelock et al. 2011). To support the child's generalized use of the targeted behavior being modeled, all communication and interaction attempts should be encouraged and reinforced. The target behavior should be demonstrated about 75–80% of the time before determining acquisition, and at least two observations of the video should occur before learning acquisition is assessed (Charlop-Christy 2004; Prelock et al. 2011).

Efficacy Information

Dowrick and colleagues first described the effectiveness of video modeling when they used this intervention to facilitate skill development in children with a variety of disabilities (Dowrick and Dove 1980; Dowrick and Hood 1981; Dowrick and Raeburn 1995). Charlop-Christy and her colleagues then applied video modeling to children with ASD (Charlop and Milstein 1989; Charlop-Christy and Daneshvar 2003; Charlop-Christy et al. 2000; LeBlanc et al. 2003). Over the last 25 years, research has investigated a variety of outcomes in the areas of communication, social, and academic skills following implementation of video modeling for children with ASD.

Spontaneous requesting (Wert and Neisworth 2003), recognizing emotions in speech and facial expressions (Corbett 2003), compliment giving, initiations and responses (Apple et al. 2005), and

language production (Buggey 2005; Charlop-Christy et al. 2000), including responding to questions and making verbal requests (Buggey et al. 1999), asking questions (Charlop and Milstein 1989), and increasing conversational speech (Charlop and Milstein 1989; Charlop-Christy et al. 2000; Nikopoulos and Keenan 2003, 2004, 2007; Ogletree and Fischer 1995; Sherer et al. 2001), have all been reported as yielding positive communication outcomes following video modeling.

A variety of social skills have also been facilitated through video modeling, including play behaviors such as reciprocal play (Nikopoulos and Keenan 2003; Sancho et al. 2010), motor and verbal sequences (D'Ateno et al. 2003), independent play (Charlop-Christy et al. 2000), play-related comments (Taylor et al. 1999), and socio-dramatic play (Dauphin et al. 2004; Nikopoulos and Keenan 2003) and more social engagement behaviors like complying, greeting and sharing (Simpson et al. 2004), spontaneous greeting (Charlop-Christy et al. 2000), and social initiations (Buggey 2005, 2013; Nikopoulos and Keenan 2004). Various aspect of theory of mind have been taught using video modeling including first-order false-belief tasks (Charlop-Christy and Daneshvar 2003) and other perspective-taking activities such as recognition of facial expressions, gestures, and intonation in the context of play (LeBlanc et al. 2003). In fact, Gena and colleagues (2005) found video modeling to be as effective as in vivo modeling in increasing affective responding (i.e., sympathy, appreciation, and disapproval) for preschoolers in the context of play with peers. Video-based group instruction was successful in increasing social initiations such as joining an activity and social awareness such as asking about another person's interest and offering assistance (Plavnick et al. 2013).

Academic classroom skills have also been supported through video modeling. Adolescents with ASD learned to solve math problems (Burton et al. 2013) after watching their successful performance. Preschoolers with ASD successfully increased their social communication in the classroom using either in vivo or video modeling (Wilson 2013).

When comparing the effects of live modeling to video modeling on increasing spontaneous greetings, conversational speech, play, comprehension following story reading, emotion recognition, and self-help skills, results favored video modeling which led to faster skill acquisition and better generalization and was more cost effective (Charlop-Christy et al. 2000). In addition, Sherer et al. (2001) found no differences between children watching themselves and children watching other children or adults when examining children's ability to respond to and ask questions.

Video modeling appears to be an evidence-based intervention that supports generalized learning and skill maintenance (Prelock et al. 2011). A review of the literature suggests video modeling is a promising intervention to support social communication and functional skills (Ayres and Langone 2005; Bellini and Akullian 2007). In fact, the National Standards Project (National Autism Center 2009, 2015) describes modeling, including video modeling, as an established intervention that increases communication, cognitive, social, play, and personal responsibility skills and decreases problem behaviors for children ages 3–18 on the autism spectrum. Additional research is needed to examine the impact of video modeling on children with more limited verbal and cognitive abilities.

Outcome Measurement

There are no specific tools or instruments suggested for measuring treatment outcomes, although most clinical researchers using this method suggest that a functional behavior assessment should occur prior to implementation to determine the targeted behaviors (Sturmey 2003), data collection should follow a single-subject design approach (Kazdin 1982), and curriculum-based measurements should be considered in assessing effectiveness across contexts (Salvia and Hughes 1990). Following these recommendations, baseline rates of behaviors should be documented and then tracked through intervention and maintenance. Graphic representations can also be made to display visual evidence of

change. Charting progress on targeted behaviors is also possible through curriculum-based measurements if team members are examining change in the context of the classroom as compared to the performance expected of other students in the classroom. Parents can have a critical role in the measurement of outcomes, particularly if the desired behaviors are primarily observed in the home, although documenting generalization of behaviors across home and school settings is ideal.

Qualifications of Treatment Providers

There is no specific training required to implement video modeling other than being familiar with the equipment and software used to create and edit the video models or video self-models. Models require the basic skills to act out a pre-determined script that is targeting the desired behavior. Parents, teachers, speech-language pathologists, and other related service providers may be required to take on primary responsibility for planning and editing the videos or particular aspects of the video depending on the targeted behaviors and the requirements for language, engagement, physical positioning, behavior, etc.

Video Prompting

Definition

Video prompting (VP) is one of the several video-based instruction strategies, and it involves a student observing an actor performing individual task steps on a video before imitating those task steps. The process is comprised of the following sequence: The student observes a single step, and then the student performs that step. The student repeats this process until all task steps are completed. Additional prompts and performance feedback are required for some individuals, and these should be faded as soon as possible to promote the independent demonstration of the skills or the independent use of the VP system.

Historical Background

Video-based instruction (VBI) is based, in part, on Albert Bandura's Social Learning Theory (Bellini and Akullian 2007). In that seminal work, Bandura (1977) posited that in addition to learning behaviors through direct experience, humans could also acquire behaviors by observing others emit behavior. Bandura reasoned that the ability to imitate others makes for efficient learning that

results in the large behavior repertoires that humans develop. Others have supported the idea that imitation is a critical feature of learning that is essential for developing a variety of important skills (Cooper et al. 2020). VBI is also based on other behavioral procedures such as task analysis, behavior chaining, and performance feedback (Banda et al. 2011).

VBI has been implemented for decades with individuals with developmental disabilities (DD), including people who experience autism spectrum disorder (ASD; Banda et al. 2011; Bellini and Akullian 2007). VBI incorporates two main strategies that include video modeling (VM) and VP; there are additional variations based on these overall VBI techniques. The main difference between VM and VP is related to the video presentation. When using VM, an interventionist plays the video of an actor performing an entire task before instructing the student to imitate what they observed on the recording. When using VP, the interventionist plays a video of one step of a task being completed by an actor prior to instructing the student to model what they viewed, and this continues until all steps have been presented using the video recordings, as well as all steps having been completed or attempted by the student (Aljehany and Bennett 2019).

VP is a VBI strategy that is used with behavior chains (i.e., behaviors comprised of multiple steps, such as making a sandwich). Earlier research suggested that people performed better when completing a behavior chain while viewing smaller portions of video compared to viewing longer video sections (Margolius & Sheffield, as cited in LeGrice 1989). LeGrice (1989), applying the aforementioned research finding, was among the first researchers to explore the effects of VP on the skill acquisition of chained behaviors among individuals with DD. In that study, LeGrice (1989) successfully used VP as part of a time delay strategy to teach individuals with intellectual disability (ID) to use a video recorder and a personal computer. Participants were given an opportunity to perform the target behaviors. If the participants did not respond, or if they responded in error, a video prompt was delivered up to three times. The researcher showed the participants a video clip of

an actor completing the corresponding task step and then asked the participants to imitate what they observed. In this sense, VP was used as a consequence strategy.

Soon after the LeGrice (1989) study, Tiong et al. (1992) examined the effects of VP when teaching individuals with ID fire safety skills (e.g., exiting a building). Similar to the LeGrice (1989) study, Tiong et al. (1992) used VP as part of a time delay strategy whereby participants were given an opportunity to respond. However, contingent upon no response or an error, the researchers showed participants a video prompt of the correct behavior, and this video was shown up to three times. Similar to the previously discussed study, VP was used as a consequence strategy. Results indicated that participants acquired the correct responses, there was evidence of generalization, and the responses maintained following the removal of the intervention.

In a later study, Norman et al. (2001) investigated VM combined with VP to teach children with DD three self-help skills including cleaning sunglasses, putting on a watch, and using a zipper to close a jacket. Norman et al. (2001) started sessions by showing a complete video model of the entire task. This video model was followed by a zero-second time delay whereby the researchers then showed participants a video prompt of the first task step to be completed. The time delay for showing participants the video prompt eventually increased to 5 sec. Results indicated that VM combined with VP was successful in teaching the students the targeted skills. In addition to these positive results, there is an important distinction between the study by Norman et al. and those by LeGrice (1989) and Tiong et al. (1992): Norman and colleagues used the VM and the VP sequence, at least initially, as an antecedent strategy rather than a consequence strategy. Although VP eventually became a consequence strategy in the Norman et al. study, this variation is notable in that the researchers implemented VP as a system to match errorless learning parameters.

Graves et al. (2005) also used VM combined with VP to teach three secondary students with ID to complete cooking tasks. Similar to Norman et al. (2001), Graves et al. (2005) initially used

VM and VP as antecedent strategies to reduce the likelihood of student errors while learning the targeted tasks. VP eventually became a consequence strategy as the study progressed, and the results indicated that the participants acquired the cooking skills with anecdotal reports of generalization and maintenance.

An additional, albeit subtle, variation of this research line was conducted by Sigafoos et al. (2005). In this study, the researchers examined VP (without the use of VM) on the acquisition and maintenance of adults with DD making a snack. Intervention sessions consisted of researchers playing a video prompt before requesting participants to complete a given step. Sigafoos et al. continued to use VP as an antecedent intervention throughout the study, and this represents an approach to VP that potentially reduces errors committed by participants. Results suggested that two of the three participants acquired and maintained the skill; however, VP was not helpful for the remaining participant.

In a follow-up study, Sigafoos et al. (2007) examined the effects of VP as an antecedent strategy to improve a daily living skill (DLS) – in this case, dishwashing – among adults with DD. The VP procedure was implemented identically to the Sigafoos et al. (2005) study. Results suggested that participants acquired the skills; however, unlike previous research, they did not maintain the skill when VP was removed. Attempts to fade VP by progressively combining steps until the procedure resembled VM were successful with two of the three participants. The remaining participant's responding was variable.

The results related to maintenance led to Sigafoos et al. (2007) questioning whether VP might lead to a level of prompt dependency for some participants. That is, some participants would continue to require video prompts to complete tasks. For some researchers, practitioners, caregivers, and students, this dependency might be of concern since the use of devices to prompt behavior might not be suitable in all settings (Sigafoos et al. 2007).

The studies described represent a sampling of the development of the VP strategy; the presentation of these studies does not imply a specific

timeline nor does it represent an exhaustive sample of the work during the timeframe of the reviewed studies. The critical point is that the tactic emerged as a means of helping individuals learn tasks comprised of multiple steps given that early research demonstrated that shorter video clips, focused on fewer behaviors, were effective when teaching people skills (LeGrice 1989). The application of VP with individuals with DD proved successful, and researchers applied variations (e.g., as an antecedent strategy and as a consequence strategy) with success. The development of VP continued during the ensuing years, and there is ample research available today to suggest that the practice is evidence-based under certain circumstances.

Current Knowledge

Over the last several decades, researchers have explored the effects of VP on the acquisition, maintenance, and generalization of skills among individuals with DD, including those people experiencing ASD with or without ID. Many of these studies have been organized into systematic reviews of the literature and meta-analyses, and our understanding of the effects of VP has improved as a result of this work.

The effectiveness of VP on the acquisition of chained behaviors has been well-documented. One of the first research teams to synthesize the research on VP was conducted by Banda et al. (2011). That research demonstrated that VP was effective for teaching a variety of chained behaviors to individuals with ASD with or without ID. In their review of the literature, Gardner and Wolfe (2013) reported that VP was effective when teaching chained behaviors to individuals with ASD. A subsequent review by Domire and Wolfe (2014) reported similar findings. In a recent meta-analysis, Aljehany and Bennett (2019) reported that VP was an effective instructional strategy for teaching DLS; their results showed the effect size of VP was in the high-moderate range. Among these review studies, the chained behaviors frequently explored were DLSs (e.g., cooking, setting tables, laundry skills, tying shoes,

and washing dishes), community skills (e.g., using debit cards), vocational skills (e.g., cleaning, making photocopies), and safety skills (e.g., exiting a building).

Maintenance and generalization of skills were noted among some of the studies in the aforementioned systematic reviews. Indeed, Banda et al. (2011) and Domire and Wolf (2014) reported that some researchers demonstrated positive results related to maintenance and generalization of skills. However, issues with maintenance were also noted in some studies. Overall, these features of learning – that is, maintenance and generalization – seem to be understudied, and additional work is needed.

In addition to the overall effects of VP, researchers have explored parameters of VP, including the perspective of the videos, the actors serving as models in the videos, differing screen sizes, and the use of other procedures as part of a VP intervention package, to name a few (Bennett et al. 2017). The perspective from which the video is recorded, and subsequently played for those receiving VP, can be from (a) a first-person, or point-of-view, perspective; (b) a third-person, or spectator, perspective; or (c) a combination of both of these. A first-person perspective shows learners a video of an actor performing a task; however, only the actor's arms and hands are in view. A third-person perspective shows students a video of the actor completing tasks from a distance such that most or all of the actor's body is in view while completing the task. Researchers have used all three perspectives across VBI studies with success. When it comes to VP, in particular, researchers have reported that the strategy has been effective using either perspective, as well as the combined perspective (Domire and Wolfe 2014). Moreover, Bennett et al. (2017) reported that there were no differences in two comparison studies whereby researchers examined differences related to the video perspectives. Notwithstanding these findings, a first-person perspective has the advantage of reducing additional stimuli that might be less relevant to task completion, and this feature could benefit individuals with ASD who are known to have issues with over-selectivity and attending to tasks (Gardner and Wolfe 2013).

Another parameter of VBI that received attention in the literature is related to the actors performing tasks in the videos. Bandura (1977) suggested that imitation of others' behaviors could be affected by the degree to which the actor, or model, is similar to the individual learning skills. In the overall VBI literature, there are numerous examples of various models used as actors in the videos, including self as the model, children as the models, and adolescent and adults as the models. In the Bennett et al. (2017) review on parameters of VBI, comparison of models was examined by researchers with inconclusive results. In some cases, self as the model (when compared to peer or adult models) was more effective for a limited number of participants. In other instances, self as the model, adult as the model, and peer as the model were equally effective (Bennett et al. 2017). In demonstration studies where the model type was not compared, there have been successful reports of VM and VP with children modeling adult actors, adolescents modeling adult actors, and adults modeling adult actors (Gardner and Wolfe 2013). Thus, specific guidance is difficult to offer at the present moment, and additional research seems to be warranted when examining the effects of model type when implementing VM or VP (Bennett et al. 2017).

In recent years, and as a result of improvements in mobile technology, researchers have investigated the effects of different screen sizes when using VBI. Among the advances in technology are the screen sizes of video playback devices. Devices used in past VBI research included televisions, desktop computer monitors, laptop computers, tablet computers, and smartphones, to name a few. To date, there are inconclusive results related to this parameter of VBI (Bennett et al. 2017). Some researchers found little differences in student performance when comparing large to small screen sizes using VM (Miltenberger and Charlop 2015), while other researchers found larger screen sizes to be more effective for participants when using VM (Mechling and Ayres 2012). Recently, Bennett et al. (2016) found that results between two different screen sizes were negligible for two participants, with the remaining

participant performing better with a larger screen size when using VP. Considering the corpus of work examining screen sizes with VBI, Bennett et al. (2016) posited that differences in student performance could be unique to the characteristics of the students or the tasks they are learning to complete.

Other intervention components have been included with VP (Aljehany and Bennett 2019; Banda et al. 2011). Some of these additional strategies include the use of voice-over instructions that accompany each video step, the use of response prompts and fading systems (e.g., least-to-most prompting, graduated guidance), and error correction (Aljehany and Bennett 2019). Voice-over instruction provides students with an auditory cue as part of the video, and the inclusion of this extra cue can help some individuals perform the demonstrated behavior (Bennett et al. 2017). However, as pointed out by Bennett et al. (2017), a few individuals seemed to perform better without the use of voice-over narration. Thus, caregivers and practitioners should record the video with narration and then test if the narration is useful to the student. Adjusting this parameter, if initially recorded, is as simple as lowering the volume (Bennett et al. 2017).

In addition to voice-over narration, researchers have examined the effects of additional response prompting and fading systems to help learners follow video prompts. In a recent meta-analysis of VP, Aljehany and Bennett (2019) reported that the use of response prompting and fading systems, as well as error correction, was needed for some participants with ASD and ID. If these extra strategies are needed, it is critical that implementers fade these extra prompts so that the videos evoke student behavior absent of additional assistance by others. Ideally, the students learn to model the video demonstrations on their own so that they can prompt their behavior, especially as they approach new tasks (Smith et al. 2015).

The promise of any VBI system, including VP, is that individuals with ASD and similar developmental disabilities learn a system that can prompt their behaviors independent of caregivers or professionals. The improvements in mobile technology (e.g., tablets, smartphones, and smartwatches)

offer the potential for greater independence as students learn to become VBI users (Smith et al. 2016). To date, however, there have been a limited number of studies whereby researchers examined the effects of VBI as a self-instruction system. In the existing research on self-instruction, implementers completed some tasks for the students while setting up the self-instruction sessions, and this limits the results of the extant data (Smith et al. 2015, 2016). Smith et al. (2016) completed one of the few studies whereby researchers demonstrated that individuals with ASD and ID could learn to self-instruct using VM on a smartphone. The results of this study are promising, but additional work is needed in this area.

Future Directions

Although the use of VP has been well-studied over recent decades, there are still areas that need to be addressed. First, many studies on the use of VP have focused on teaching DLSs. Additional work is needed to learn if VP is useful in developing other skills among individuals with ASD, including academic skills and social skills. Second, Aljehany and Bennett (2019) reported that VP was most frequently studied with adolescent and adult participants. There were too few studies and participants where researchers examined VP with elementary-aged students. Moreover, there were even fewer studies and participants that included preschool-aged children. Given these findings, additional research is needed to inform caregivers and practitioners the extent to which VP is effective with younger populations. Third, as illustrated by Banda et al. (2011), Domire and Wolfe (2014), and Smith et al. (2016), additional studies are needed to assess the generalization potential of VBI strategies, including VP. This issue is more pronounced considering that VBI strategies, paired with mobile technology, have the potential to serve as a self-instruction methodology or a self-remediation technique (Smith et al. 2016). Fourth, additional work is needed to explore methods to fade VP so that individuals perform tasks in complete independence. As Sigafos et al. (2007) argued, there could be instances in

which it is not feasible or appropriate for individuals with disabilities to use VP. For instance, some tasks, or task steps, require careful attention (e.g., construction), and the use of mobile technology as a self-instruction or self-prompting device could compromise the safety of the person performing the task or others nearby. Finally, as technology continues to advance, becomes more portable, and begins to simulate reality (e.g., portable devices used in virtual reality simulations), the integration of VP tactics with this technology becomes possible. However, research into how such technology affects individuals with ASD, the practicality of using such technology in home and community settings, and the feasibility of integrating the instructional strategies with advance technology is needed (Pham et al. 2019).

Although additional work is required to refine some of the parameters surrounding the use of VP, as well as research on integrating VP with more advanced technological developments, the practice is well-suited for helping people with ASD. Years of research have demonstrated that the strategy is useful for developing skills among this population of learners. Caregivers and teachers should consider using this strategy when circumstances permit.

Video Tape Analysis Studies

Definition

This entry on videotape analysis studies considers how researchers use video to study autism, especially in terms of diagnosis, skill assessment, behavioral expression, and lived experience. The studies primarily represent research from the United States.

Historical Background

Live observation of human behaviors and interactions is a basic investigative tool used in the humanities and social sciences, and video recording is now used as an addition to or substitute for this research activity. Ethnographic and

ethnomethodological theories and methods are often manifested in video footage that is spontaneous, with wide-angle shots of social activities occurring in their typical settings. It can be analyzed in terms of conversational and discursive features, meaning-making actions and processes, social activities and routines, and speech acts and events, for example, which are often represented in the form of transcripts. Psychological theories and methods are often manifested in video footage that is considered semi-structured or structured, where spontaneous behaviors are captured and/or elicited in prearranged scenarios. Depending on the behavior in question, close or wide framing of shots occurs. It can be analyzed using discrete behavioral coding, or translating an observation of gaze, facial expression, gesture, or word production, for example, into a number, where any type of outward behavior can be defined and measured in an effort to predict and/or understand its relationship to another behavior. Erickson (1986) argues that ethnographic/ethnomethodological approaches are “interpretive” or focused on how meaning is made in human life and psychological approaches are “positivistic” or focused on cause-and-effect relationships between human behaviors. The former, he says, primarily intends to “particularize” human experience or locate it within a historical and social time and place. The latter, he continues, primarily intends to “generalize” human experience or identify patterns of behavior that may hold true despite environmental influences. Depending on researchers’ training and the phenomenon they want to investigate, they may thus approach the collection and analysis of video recording differently. However, given the permanent documentation of human behavior that video provides, a combination of such approaches to recordings may also be applied.

Current Knowledge

Video to Diagnose (Retrospective and Prospective)

One of the most representative types of autism video analysis studies is that of the retrospective use of home videos for the purpose of

investigating the emergence of autism in infants. Faced with questions about the possible early expression of behavioral differences and how, in particular, that might correspond to early diagnosis and intervention, researchers often turn to families for help. The most commonly cited study, by Osterling and Dawson (1994), compared the home videos of 11 children with autism and 11 neurotypical children as they celebrated their first birthdays. Though not the first researchers to use home videos (see the same article for a discussion of the earliest work by Massie in the late 1970s), their decision to focus on such an event allowed them to match children from the two groups in terms of activity, age, and setting, which strengthened their research design in comparison to previous studies. As a result, their findings still receive significant attention. In particular, the absence of social interaction action behaviors, especially orienting to names and others, pointing, and showing objects, predicted a later autism diagnosis. Adding to the scope of previous studies, Baranek (1999) also used home videos to measure sensory-motor functioning in addition to social functioning in 32 infants who were divided into groups with neurotypical development or a later diagnosis of autism or developmental delay. Focusing on scenarios of social play, Baranek determined that between 74% and 85% of the time-specific variables, including mouthing and playing with objects and bodily posturing, significantly predicted which developmental group the infants would later fit into. This reflected similar findings from earlier video analysis by Losche (1990). Baranek thus recommended using sensory-motor functioning measurements as supplements to screening tools for autism. Similarly, Colgan, Lanter, McComish, Watson, Crais, & Baranek (2006) found a correlation between less variety of gestures in infancy and later autism diagnosis. These retrospective studies used behavioral coding to measure and analyze video data. For example, Adrien, Lenoir, Martineau, Perrot, Haneury, Larmande, & Sauvage (1993) used a standardized assessment to code behavioral functioning on a 0–4 scale. Meanwhile, other studies developed original coding procedures based on behavioral categories

identified in previous studies. Whether building off of existing measures or meeting the needs of a particular study, retrospective coding of video produced evidence that early behavioral differences could be identified in a way that might predict a later diagnosis of autism. It also provided the foundation for researchers to begin prospective video studies and to test the validity of these findings.

Unlike the retrospective studies, prospective studies often use video collected from structured assessments and/or as a supplement to other measures (these assessments and measures will be discussed in more detail in the next section). Driven by evidence that autism is usually genetically based, such studies largely examine the behavior of infant siblings of older children who have been diagnosed with autism. In recent work, Ozonoff, Iosif, Baguio, Cook, Hill, Hutman, Rogers, Rozga, Sangha, Sigman, Steinfeld, & Young (2010) coded the frequency of social behaviors and engagement from video of standardized visual subtest for 25 infant siblings who were later diagnosed with autism and 25 gender-matched neurotypical children at 6, 12, 18, 24, and 36 months. After 12 months of age, they found significantly less sharing of gaze, smiles, and vocalizations with examiners in the autism group. Using this same sample of children, Rozga, Hutman, Young, Rogers, Ozonoff, Dapretto, & Sigman (2011) coded nonverbal communication and social interaction abilities of neurotypical infants and infant siblings who either went on to receive a later diagnosis of autism or not. In a lab setting, they videotaped semi-structured play between caregivers and children and a social communication assessment. This permitted coding of gaze, joint attention, smiles, and vocalizations at 6, 12, 24, and 36 months for most of their 167 subjects. Like Ozonoff et al. 2010 they found that autism symptoms were not identifiable before 12 months. In line with these findings, Hutman, Rozga, DeLaurentis, Barnwell, Sugar, & Sigman (2010) found a comparatively lower reaction to distress behaviors between the ages of 12 and 36 months for infant siblings later diagnosed with autism. Furthermore, Wetherby, Woods, Allen, Cleary, Dickinson, & Lord (2004)

also used video from a communication and symbolic skills assessment for children between the ages of 18 and 21 months and found that at least nine behaviors indicated autism versus other atypical and typical development. This included difficulties with coordinating and orienting gaze, responding to one's name, repetitive movements of the body or with objects, and unusual prosody. In sum, prospective videotape studies further specify the findings of retrospective home videos and lend more support to the validity of early behavioral differences being predictive of a later autism diagnosis.

Video to Assess and Treat

As indicated in the previous section, semi-structured and structured assessments that are administered in a lab setting are often used in combination with video as well as other measures in large-scale, multifaceted, and sometimes multi-site studies. In order to facilitate the exchange of information, researchers often use the same or similar protocol and video coding procedures. Some of the most common, replicated videotape studies for autism have measured emotional expression, engagement states, joint attention and other nonverbal communication, functional and symbolic play levels, verbal abilities, and coordinated or synchronized interactional behaviors.

Many different semi-structured and structured assessments are used to measure a variety of domains of functioning in children with autism. The behaviors, when coded across time, can also be used to evaluate the efficacy of a treatment approach. For example, an early intervention targeting joint attention may measure the child's joint attention at pre- and post-intervention to evaluate program efficacy. A few of the most noteworthy assessments include the Early Social Communication Scale (ESCS; Mundy et al. 1986), the Structured Play Assessment (Ungerer and Sigman 1981), maternal synchrony (Siller and Sigman 2008), and joint engagement coding (Adamson et al. 2009). The ESCS is a semi-structured assessment that provides social communication probes to children with autism and is later coded for initiations and responses to joint

attention. The Structured Play Assessment is also a semi-structured assessment that provides children the opportunity to display functional and symbolic play acts; frequency and type of play acts are coded from the videotape. Both the maternal synchrony code and joint engagement coding systems are coded from a brief videotaped mother-child interaction where mothers and children are instructed to “play as they normally would” with their child. The maternal synchrony code focuses on several dimensions of the interaction including maternal indicating behaviors, maternal verbal behaviors, and the child’s toy-directed attention. The joint engagement coding system is a state coding system that compiles the duration of time that the child’s attention is directed to another person, objects, or shifting attention between the two. These measures have been applied to the study of children with autism both using cross-sectional and longitudinal designs (Siller and Sigman 2008), as well as used as measures of treatment outcome in early intervention research (Kasari et al. 2006, 2008, 2010).

Researchers also integrate video-based analysis to compare and potentially improve autism intervention and treatment. For example, Rogers, Hayden, Hepburn, Charlifue-Smith, Hall, & Hayes (2006) determined that Denver Model and PROMPT therapies produced similar language outcomes. Additionally, Kasari et al. (2010) demonstrated the positive impact of parent-mediated intervention on toddlers’ communication skills. While video is also used in various ways to treat autism-related issues (i.e., reflecting on videos of oneself to learn adaptive social skills), those are beyond the scope of this entry.

Video to Contextualize, Describe (Naturalistic: Generalizing, Particularizing)

Naturalistic videos of spontaneous behaviors in real-life social settings provide a way for researchers to explain their findings in relation to the varied expression of lived experience. When collected by researchers who apply ethnographic or ethnomethodological approaches, videos function as a form of documentation of everyday life. They can be transcribed in terms of nonverbal and

verbal features and closely analyzed in terms of the resources that individuals use to make sense of a given social moment. Ochs, Kremer-Sadlik, Sirota, and Solomon (2004), for example, demonstrate that video analysis conducted within an overall ethnographic study can be used to further investigate how specific children with autism cope with aspects of social functioning that are culturally and historically situated. They apply conversation and discourse analysis, provide detailed descriptions of social organization, and identify how the features of conversational sequences, specific situations, and implied cultural norms can either provide support or limitations for individuals with autism. Similarly, Ochs, Solomon, and Sterponi (2005) apply the same style of video microanalysis to a cross-cultural comparison of autism therapy. They find that treatment outcomes can be affected by body positioning, speech tempo, voice pitch, and other features of communication that are often culturally specific and subconsciously enacted. In the same analytic tradition, Kremer-Sadlik (2004) demonstrates in part how caregivers use question and answer sequences and reformulations of speech to enhance the participation of their children with autism in family activities. Similarly, Maynard (2005) analyzes the administration of a standardized assessment of commonsense reasoning. He demonstrates how an apparently straightforward question that is presented by examiners to children with autism is actually underpinned by different types of practical logic that impact children’s responses and the meaning of the exam’s results. As previously mentioned, such studies represent an effort to “particularize” (Erickson 1986) the experience of autism, and they typically focus on very few cases or individuals at a time.

Naturalistic video can also be used to “generalize” (Erickson 1986), though sometimes the social situations may be somewhat structured. In such cases, spontaneous interactions may be transcribed as in the above studies, and then verbal features may be quantified and statistically analyzed. Also, the behaviors of larger groups of individuals or “samples” may be coded frame-by-frame, in specific categories or intervals, or

for specific durations or frequencies and then statistically analyzed. For example, Tager-Flusberg, Calkins, Nolin, Baumberger, Anderson, & Chadwickdias (1990) compared the language acquisition of six children with autism and six with Down syndrome by analyzing 100 samples of their spontaneous speech while playing with their mothers at home over a span of 14 months. In part, they measured lengths of utterances, word order, and word usage and found that the children in the study followed the same developmental trajectory for language as neurotypical children. Similarly, Capps, Losh, and Thurber (2000) compared the language of 13 children with autism, 13 with Down syndrome, and 13 neurotypically developing while telling stories from a book and participating in a semi-structured conversation with an intervention. They applied a preexisting transcription system to analyze speech structures and an original coding system to analyze evaluative practices in storytelling. After a statistical analysis, they determined that the discreet components did not significantly differ between the groups, but how children with autism linked them did. Similarly, from transcripts, Losh and Capps (2006) coded emotional experiences recounted by neurotypical children and those with autism during the administration of a conversation-based emotion elicitation procedure. Using a discourse analysis perspective in combination with a 0–3 scale of situational appropriateness, they identified statistical differences in aspects of how the two groups interpreted and represented their emotional experiences. Swensen, Kelley, Fein, and Naigles (2007) also used video documentation to investigate the relationship between gaze and word-order comprehension in very young children with autism and neurotypical development. Such studies seek to find general patterns of behavior within more natural settings in order to produce findings that may have universal implications.

Future Directions

As technological advances make video equipment and related analytic software more accessible,

affordable, and efficient, videotape studies present promising future directions. In addition to the refinement of measures based on naturalistic, semi-structured, and structured video for purposes of diagnosis, assessment, description, intervention, and treatment of autism, such studies support creative, holistic, and representative approaches. For example, bridging a divide between qualitative and quantitative research paradigms, video facilitates mixed-method designs. Most often, this means that video is being used to capture human interaction in natural environments, which is then coded and/or transcribed. While the reality is that such uses of video are not usually truly combining methodologies but rather standing them side by side, they are nevertheless a reflection of researchers attempting to apply and connect their work to real-world settings. This can be seen in studies that videotape spontaneous interactions in clinics, homes, and schools, for example, and result in generalizable findings that may be used to improve educational and intervention services (Grey et al. 2007; Kasari et al. 2006; Tardif et al. 1995). This is also seen in studies that use videos to document and detail specific behaviors in specific contexts, as with the Thunberg, Ahlsen, and Sandberg (2007) description of four children's use of speech-generating devices in their homes and with the Stribling, Rae, and Dickerson (2007) description of a girl's use of different forms of repetition in her classroom. Video creates additional opportunities as well. In terms of investigating issues for which clinical and standardized assessments may be problematic (i.e., assessing intelligence in nonverbal individuals with autism or relating daily functioning capacities with cognitive test scores), ecological validation, or the comparison of assessment rationale/scores with that of everyday behaviors, is made possible. This can provide clinicians with more information about how standardized measures might relate to daily life. Seal and Bonvillian (1997), for instance, correlated standardized measures of apraxia to the videotaped sign language production of 14 children and adolescents with autism in classroom settings and determined a relation between movement ability and vocabulary size. Though their study was not designed for

purposes of ecological validation, it provides an example of potential applications. Such studies may help to modify or supplement standardized assessments, if needed. Finally, not only researchers can collect video. The involvement of individuals with autism, caregivers, teachers, and others in research may be facilitated by the exchange of personal videos, making collaborative efforts more common.

Description

The Vineland Adaptive Behavior Scales, Third Edition (Vineland-3; 2016) is the third revision of the first standardized measure of adaptive behavior, the Vineland Social Maturity Scale (VSMS) (Doll 1935). Adaptive behavior can be defined as a collection of conceptual, social, and practical skills that are necessary to live independently and function appropriately in one's daily environments. The Vineland Adaptive Behavior Scales (Vineland ABS), the first revision of the VSMS, was published in 1984 (survey and expanded forms) and 1985 (classroom edition). The second revision, the Vineland II, was published in 2005 (survey and parent forms).

The Teacher Rating Form of the Vineland-II was published in 2006, and the Expanded Interview Form was published in 2008. Together, the Vineland ABS, Vineland II, and Vineland-3 are the most widely used measures of adaptive behavior.

The Vineland-3 assesses three core adaptive behavior domains: communication, including receptive, expressive, and written communication; daily living skills, or the ability to take care of one's daily needs, which include personal (e.g., dressing and hygiene), domestic (e.g., household chores), and community (e.g., managing money) activities; and socialization, or the ability to form developmentally appropriate interpersonal relationships, engage in developmentally appropriate play and leisure activities, and demonstrate developmentally appropriate coping skills. The gross and fine motor skills of children ages 9 and younger can be assessed within the motor skills domain. However, to be consistent with the Diagnostic and Statistical Manual, Fifth Edition (DSM-5) criteria for intellectual disability, which excludes motor impairments, the motor skills domain of the Vineland-3 is now optional. In addition, the optional maladaptive behavior domain, which measures maladaptive behaviors that may interfere with an individual's adaptive functioning, is now available for the Interview, Parent/Caregiver, and Teacher Forms. The maladaptive behavior domain includes optional maladaptive internalizing (e.g., symptoms of anxiety and depression), externalizing (e.g., symptoms of hyperactivity and impulsivity), and critical items that measure more severe maladaptive behaviors but are not scored as a subscale or composite (e.g., suicidality, fire setting).

Like the Vineland II, the Vineland-3 has three comprehensive administration forms: the Interview Form (formerly Survey Interview and Expanded Interview Forms combined), the Parent/Caregiver Form (formerly Parent/Caregiver Rating Form), and the Teacher Form (formerly Teacher Rating Form). The Vineland-3 also includes a brief domain-level administration version of each of the three comprehensive administration forms. The brief Domain-Level Forms consist of fewer items than the comprehensive forms and are generally used to determine diagnostic eligibility for

intellectual disability. The six forms are available for administration via paper and pencil or online using Pearson's Q-global™ platform, an online-testing platform that provides automated scoring and reporting. The Interview and Parent/Caregiver Forms can be administered for individuals across the lifespan (from birth through age 90 years). The Teacher Form can be administered to children ages 3 to 21 years. The brief Domain-Level Forms can be administered to ages 3 to 21 years.

The Vineland-3 yields an overall adaptive behavior composite (ABC) standard score (mean of 100 and a standard deviation of 15) as well as standard scores for each of the adaptive behavior domains, percentile ranks, adaptive levels, and stanines. The communication, daily living skills, socialization, and motor skills domains are comprised of age-based subdomains. In the comprehensive versions of the Vineland-3, *v*-scaled scores (mean of 15 and an *SD* of 3) and age equivalents are also derived for the subdomains. The Domain-Level Forms yield an ABC and domain standard scores.

The Vineland ABS is the most commonly used measure of adaptive behavior among individuals with autism spectrum disorder (ASD). Adaptive behavior is an important determinant of prognosis in ASD. Given the hallmark features of ASD, it is not surprising that individuals with ASD exhibit deficits in their adaptive behavior. Researchers have attempted to uncover a typical profile of adaptive behavior among individuals with ASD. However, the pattern of adaptive behavior observed among individuals with ASD differ based on several important factors, including participant's cognitive abilities and age as well as the research methodology (e.g., use of standard scores or age-equivalent scores). Generally, individuals with ASD who have average or above average cognitive abilities demonstrate a profile of adaptive behavior that is characterized by relatively strong daily living skills, significant deficits in socialization skills, and moderate deficits in communication (Kanne et al. 2011). While this profile of adaptive behavior is often referred to as the "typical" autism profile of adaptive behavior, other profiles of adaptive functioning have been found among individuals with ASD. For example,

the Vineland-II profiles of toddlers with below average cognitive functioning are characterized by higher socialization skills followed by lower communication and daily living skills (Ray-Subramanian et al. 2011). To date, no studies investigating the adaptive behavior of individuals with ASD using the Vineland-3 have been published. Of notable importance is the significant gap between cognition and adaptive functioning in individuals with ASD without cognitive impairment that appears to be greater in older vs. younger individuals (e.g., Klin et al. 2007; Kanne et al. 2011). Yet, this gap does not appear to exist in individuals with ASD who have cognitive impairment. In fact, recent studies actually show adaptive skills in these individuals to fall above cognitive level (e.g., Perry et al. 2009; Kanne et al. 2011).

Historical Background

The Vineland-3 measures the construct of adaptive behavior. Adaptive behavior is an age-based construct that is rooted in the definition of intellectual disability (formerly mental retardation). The Vineland ABS, (Sparrow et al. 1984a, b, 1985) represented a significant revision of the VSMS (Doll 1935). The Vineland II (Sparrow et al. 2005, 2006, 2008) and Vineland-3 are revisions of the Vineland ABS. The revision from the Vineland-II to the Vineland-3 included updated norms and major content updates (e.g., modified items and new items). These content updates were made to improve the cultural sensitivity of items and to reflect cultural changes and new scientific knowledge of developmental disabilities since the publication of the Vineland-II. Additionally, the items on the Parent/Caregiver Form were reworded to reflect a fifth-grade reading level. For this reason, the Interview and Parent/Caregiver Forms were normed separately, unlike the Vineland-II where they were normed together given the identical wording of items.

Unlike previous versions of the Vineland, the Vineland-3 can be administered online using Q-global™, which provides computerized scoring and reporting for both online and paper-and-

pencil administrations of the Vineland. In the online administration of the Vineland-3, the program calculates basals and ceilings, and suggests additional probes and interview questions to improve the ease of administration. Score reporting includes item-level comparisons that are provided to monitor progress and to make interrater comparisons. Furthermore, intervention planning recommendations are provided at the item-level.

Psychometric Data

The Vineland-3 was standardized on 2560 individuals from birth to 90 years of age. The standardization sample was stratified according to the 2014 US census on sex, race/ethnicity, individuals' or parents' education level, and geographic region. Additionally, data were collected on seven clinical samples that align with the Individuals with Disabilities Education Act (IDEA) disability categories. The seven clinical samples include autism, developmental delay, emotional disturbance, intellectual disability, specific learning disability, speech or language impairment, and all other IDEA disability categories. Research suggests that individuals in these clinical samples often demonstrate distinct patterns of adaptive behavior on the ABS that may discriminate between groups.

The Vineland-3 has strong psychometric properties. Interrater and inter-interviewer reliability coefficients ranged from 0.70 to 0.81 for the Comprehensive Interview Form and 0.69 to 0.84 for the Domain-Level Interview Form. Internal Consistency reliability ranged from 0.90 to 0.98 for the Comprehensive Interview Form and from 0.86 to 0.97 for the Domain-Level Form. For individuals ages 13 and older, test-retest reliabilities for the Comprehensive Interview Form ranged from 0.81 to 0.92 and from 0.73 to 0.88 for the Domain-Level Form. These represent good to excellent levels of reliability by the criteria of Cicchetti and Sparrow (1981); whereby: <0.40 = Poor; 0.40–0.59 = Fair; 0.60–0.74 = Good; and ≥ 0.75 = Excellent levels of chance-corrected interrater agreement; and for internal consistency,

whereby <70 = Poor; 70–79 = Fair; 80–89 = Good; and 90 and above = Excellent (Cicchetti 1994).

The validity of the Vineland-3 has been examined based on the content, structure, and relationships with other measures of adaptive behavior, including the Vineland-II and the Adaptive Behavior Assessment System, Third Edition (ABAS-3), as well as measures of developmental functioning (e.g., the Bayley Scales of Infant Development, Third Edition).

Clinical Uses

The Vineland scales are most frequently used to evaluate whether an individual meets diagnostic criteria for intellectual disability, as an individual with intellectual disability must have significant deficits in both their cognitive and adaptive functioning. Recently, the Vineland scales have been used to aid in the diagnoses of many disorders beyond intellectual disability, including ASD. Because the Vineland-3 measures adaptive behavior from birth onward, it is an ideal tool for developmental evaluations. In addition to assisting with diagnostic classifications, the Vineland-3 can be useful in program planning and evaluation. Although all forms of the Vineland-3 can be used in program planning, the comprehensive versions of the Vineland-3 cover a much broader range of adaptive behaviors that can be identified and targeted for intervention than the Domain-Level versions. There is also a new Intervention Guidance that examiners can use to determine specific adaptive delays to work on in intervention programming. Research suggests that interventions that aim to improve specific adaptive behaviors in high-functioning individuals with ASD may lead to better outcomes than those that target autistic symptomatology (e.g., Farley et al. 2009). One of the goals of most interventions is to improve how well an individual functions in everyday life, therefore, the Vineland-3 is an excellent progress monitoring tool as it is sensitive to small changes in adaptive functioning and can be used more frequently than other assessment tools (e.g., cognitive measures). The

Vineland scales are commonly used measures of adaptive functioning in research studies. In fact, the Vineland scales are the most commonly used adaptive behavior measure in the extant ASD literature. The Vineland-3 is anticipated to be as commonly used in future research as its predecessors. It should also be noted that the Vineland Adaptive Behavior Scales have been designated by the National Institutes of Health's National Database for Autism Research as the adaptive behavior instrument of choice for multisite studies of Autism.

Violence and ASD

Definition

Violence is defined as the purposeful and malicious injury of another person (Blackburn 1993).

From a behavior analytic perspective, it can present in multiple expressions, be preceded by various antecedents, and be maintained by numerous consequences. Instrumental violence refers to acts that are goal oriented, measured, and dispassionate (Berkowitz 1993). Expressive violence is characterized by impulsivity and mercurial emotions and may be in response to an intolerable level of physical or emotional dysregulation (McGuire 2008).

Historical Background

Violence is not a core feature of autism spectrum disorder (ASD) and is not our intent to vilify people with ASD. Indeed, people with disabilities are three times more likely to be victims of nonfatal crimes than people without disabilities. A reported 94% of people with Asperger's syndrome (AS) have been the victims of bullying (Little 2002). According to a report from the US Department of Justice (Harrell 2015), people with disabilities were the victims of 1.3 million violent crimes in 2012. This included the crimes of assault (simple and aggravated), rape, sexual assault, and robbery. With that context in mind, there are times when people with ASD do come in contact with the criminal justice system. When people on the autism spectrum do commit violence, this may be due to a multitude of factors related to their ASD including lack of access to circumscribed interest, violation of a routine, response to stress, sensory response, a circumscribed interest in violence, communication challenges, and difficulties reading social situations. Substance abuse and comorbid psychopathology confer significant increased risk of violent offending (Langstrom et al. 2009).

What remains unclear is the prevalence of people with ASD who commit violent crimes relative to their prevalence in general society. What factors place a person with ASD at risk to engage in a violent act and are these the same risk factors that confer increased risk of violence in the neurotypical population?

Prevalence in the Criminal Justice System

People with ASD are not inherently violent, though they may be overrepresented within the criminal justice system relative to their proportion in general society. The difficulty with making this assertion confidently lies, naturally, in a current lack of solid data. There are, however, a number of important aspects of sampling and psychological assessment – specifically, its deficiencies with regard to ASD – that suggest the overrepresentation of people with ASD within the criminal justice system is possible and perhaps likely.

A 2014 study demonstrated the difficulty of finding reliable samples of adult offenders with ASD (Allely et al. 2014). Here the authors examined a large group of serial and mass murderers for evidence of psychosocial stressors such as abuse or neglect, head injury, and ASD. While the authors made an admirable attempt to source their work with databases, books, and peer-reviewed articles, the resulting ASD condition remained overly broad, with the categories “definite,” “highly probable,” and “possible” based, out of necessity, on some amount of conjecture from source data.

The age of a person with ASD presents another sampling issue. As assessment and diagnosis of ASD has become much more widespread, public perception is that the prevalence of ASD in the general population is increasing. This is likely not the case, as wider availability of qualified diagnostic professionals, broader diagnostic criteria, and better record keeping all contribute to a rise in both prevalence and incidence estimates (Elsabbagh et al. 2012). A recent epidemiological study in the UK found that indeed, the prevalence of ASD appears to be consistent across age groups (Brugha et al. 2011). When we consider this in light of the fact that youth with ASD are, at least in some jurisdictions, less likely to be prosecuted due to their diagnosis (Cheely et al. 2011), we must also consider the possibility that older adults, who are less likely to have been diagnosed, are also unlikely to have had ASD presented as a mitigating circumstance in prosecution. The prevalence of ASD among those within the criminal justice system may be higher than the general population due to lack of diagnosis because of

age, and the lack of diagnosis itself presents a problem for estimation sampling.

Tools for the assessment of violence risk are an important part of the clinician’s toolkit. They have seen a number of refinements over the last five decades, with statistical prediction of risk in the second generation of assessments, the inclusion of dynamic risk factors (e.g., substance abuse, interpersonal conflict) in the third generation, and integration with interventions and assessment of rehabilitation progress in the fourth generation (Campbell et al. 2009). While Campbell et al. and others have demonstrated the utility of dynamic factors in assessment of neurotypical populations (Schwalbe 2007; Walters 2006), it should be noted that exactly how dynamic factors affect the likelihood of violence in persons with ASD is not well understood. The result is that a clinician who wishes to assess the risk of violence in a person with ASD either realizes he lacks a complete set of tools for doing so or uses an assessment that does not have demonstrated validity with ASD populations.

Clinical judgment can be utilized to assess risk of violence, and this was in fact the basis for first-generation assessments. But it is prone to error and bias (Grove et al. 2000). Compounding this is a possible pattern: People with ASD may be more likely to self-report violent behavior than other types of law-breaking behavior (Woodbury-Smith et al. 2006), resulting in a higher judgment-based violence risk assessment.

Risk Factors

In criminology, risk predictor variables are dynamic factors that include the consideration of “risk of harm” and “risk level.” Risk of harm reflects the extent and nature of the behavior that may occur. Risk level is a measure of the likelihood of the behavior occurring (McSherry 2004). Kawakami et al. (2012) found that for people with ASD, risk of engaging in criminal behavior was significantly correlated with a history of abuse and neglect as well as a late diagnosis and resultant delayed onset of services.

In a UK study of 16 adults with a clinical diagnosis of Asperger’s who had been in contact with the criminal justice system due to offending

behaviors, Allen et al. (2008) identified behavioral difficulties as well as precipitating and predisposing factors related to the commission of criminal acts. Utilizing a project-created questionnaire administered to service providers involved with the participants, the researchers identified the following extant behavioral difficulties: verbal aggression (88%), physical aggression (75%), property destruction (69%), displaying sexually inappropriate behavior (38%), substance abuse (38%), and overactivity (38%). The service providers also identified the following underlying factors which they believed predisposed the people with ASD to commit crimes: lack of concern for others (94%), social naivety (88%), lack of awareness of outcome (82%), impulsivity (63%), misinterpretation of rules (63%), and obsessional interests (44%). Factors that occasioned offending behaviors included social rejection (69%), bullying (50%), sexual rejection (50%), family conflict (50%), decline in mental health (31%), changes of residence (25%), change in care provision/support (19%), and grief (13%). The cumulative effect of stress was identified most often as the immediate trigger for an offending behavior.

Current Knowledge

Instrumental Violence

Instrumental violence involves acts that are likely to be perpetrated in an emotionally detached way and represent a means to an end behavior (Harkins et al. 2012). The following features of ASD may be implicated in the commission of acts of instrumental violence.

Violation of a Routine/Lack of Access to Circumscribed Interest

Ehlers and Gillberg (1993) noted that people on the autism spectrum often enforced rigid routines not only on themselves but on others as well. In a study of patients on the autism spectrum in a forensic psychiatric setting, Hare et al. (1999) found that 84% had nonfunctional routines which they adhered to in an inflexible manner.

These routines included holding sticks in each hand, listening to the same music over and over, touching things, and flushing toilets. The study also examined differences in circumscribed interests and routines between patients with and without ASD. Statistically significant between groups differences were found ($X^2 = 115.40$ df 2, $p < .0001$). When these routines are violated, a person on the spectrum may engage in by-all-means-necessary behavior to maintain that routine, resulting in harm to themselves or others (Hare et al. 1999).

An all-consuming preoccupation with circumscribed interests and the denial of access to those interests may also serve as a reliable trigger for violence (Barry-Walsh and Mullen 2004). Haskins and Silva (2006) posit that circumscribed interests combined with deficits in theory of mind (ToM) and weak central coherence may result in the development of intense and fixated interests uninhibited by future consequences and social norms that result in criminal behavior. Moreover, differences in perspective taking and executive functioning (Allen et al. 2008) may place them at risk for not considering the impact of their behavior on others or the legal consequences of their actions.

Circumscribed Interest in Violence

Hare et al. (1999) found that 25% of the forensic patients with ASD in their study had circumscribed interests in violence, including Nazism. In some of the cases, the violent interests were connected to the crime committed.

On December 14, 2012, Adam Lanza, a young man on the autism spectrum and comorbid mental health issues, shot and killed his mother with a .22 caliber rifle. He then drove to Sandy Hook Elementary School. He was heavily armed and shot through the school's security doors. He shot and killed the school principal and psychologist. He entered two first grade classrooms and shot and killed a total of 20 children and four adults with a Bushmaster rifle. Adam Lanza died of a self-inflicted gunshot wound to the head (Sedensky 2013).

Lanza's circumscribed interests included mass killings in general and the Columbine school

massacre in particular. He was trained in the use of high-powered weapons and had easy access to guns and ammunition. Lanza had a history of being bullied and difficulty at school. He had poor relationships with his family and an absence of friendships. Mental health professionals who had provided services for Lanza reported that there was nothing in his behavior that could have foreseen his actions, but a search of his home revealed that Lanza had an intense preoccupation with mass shootings. Lanza's circumscribed interest in violence appears to have started as early as elementary school, when in fifth grade he wrote a story entitled "Big Book of Granny." In this story, Granny hides a gun in her cane and shoots people, including children. Among the evidence found in his home was an Excel spreadsheet of mass murders dating back to 1891 that described mass murders and the number of casualties. A second spreadsheet was found that read like a task analysis of how to commit a mass murder (Sedensky 2013).

Expressive Violence

Expressive violence describes acts that are impulsive and reactive and may result from unendurable levels of sensory and physiological arousal that can exacerbate communication challenges. The following features of ASD may be implicated in the commission of acts of expressive violence.

Sensory Response

The DSM 5 (APA 2013) includes hyper- or hypo-reactivity to sensory input as part of the diagnostic criteria for ASD. This includes tactile defensiveness, atypical reactions, and at times extreme distress in response to sensory input. Sensory impairments combined with co-occurring intellectual disabilities and psychiatric disorders render a person more susceptible to developing problem behavior (Carvill 2001). There have been cases in which sensory processing challenges have been implicated in the commission of violent acts by people with ASD. Mawson et al. (1985) describe a man with ASD who engaged in an act of aggression toward a barking dog and its owner as the result

of his sensitivity to high-pitched sounds. Schwartz-Watts (2005) describes a man with ASD who shot and killed an 8-year-old after the boy ran over his foot with a bicycle. The courts ruled that tactile defensiveness precipitated the violent behavior. These cases demonstrate that untenable sensory experiences may lead to a response of such significant magnitude that it results in a criminal act.

Communication Challenges

Impairments in receptive communication can make it difficult for the person with ASD to understand what is being asked of them, while deficits in expressive communication can make it difficult to get their wants and needs met. Difficulties in the use and understanding of nonverbal behaviors may set the stage for misunderstandings with others and have the potential to negatively impact the ability to accurately read social situations. Combined, these communication challenges may lead to confusion, stress, and irritation which can be expressed as problem behavior (Dominick et al. 2007). Stress has a deleterious effect on the ability of a person with ASD to comprehend and utilize their language which can often result in aggressive acts as an alternative form of communication (Baron 2006).

Difficulties Reading Social Situations

In the general population, the social features that place people at risk for a propensity toward violent behavior later in life include poor social skills, poorly developed social networks, and defiance of authority (Farrington and Loeber 2000). A core feature of ASD is a qualitative impairment in social interactions and delays in the development of social reasoning. People with ASD experience challenges establishing and maintaining friendships, have difficulty interpreting social cues, and often engage in improper social behaviors (Siponmaa et al. 2001). While it is more likely that people with ASD will be duped into victimization as the result of their social naiveté, there are times when their misunderstanding of social rules and misreading social cues may lead them to commit an act of violence (Murrie et al. 2002). Barry-Walsh

and Mullen (2004) describe the case of a man who attempted to choke a young woman after she rebuffed his sexual overtures.

It is essential to reiterate that violence is not a core feature of ASD. The core features of ASD including social, communication, sensory, and behavioral challenges may render the person more vulnerable to environmental triggers, which could result in acts of violence.

Future Directions

It is clear that the features of ASD can lead people with the disorder to commit acts of violence that are qualitatively different from those committed by people without ASD in terms of the triggers and topography. Much more study of both populations within the criminal justice system is necessary to accurately determine proportional rates of incarceration for people with ASD and to work toward just mitigation in sentencing and prevention of recidivism. Future research should focus on the expression of behavioral challenges and associated features endemic to autism which might indicate future acts of violence. This could serve as a mechanism to develop appropriate interventions with a greater likelihood of success in reducing recidivism, as they consider the underlying mechanisms specific to ASD that resulted in violent behavior.

Additional research is also needed to understand the similarities and differences that exist in risk estimation between the population of offenders with ASD and comorbid psychiatric conditions and offenders who represent the neurotypical population. Current risk assessments do not consider factors unique to ASD, and data from this research would ultimately inform (perhaps transform) risk assessment procedures and guide more accurate understanding and communication of these risks.

Violent/Criminal Behavior in Autism

Definition

Criminal behavior refers to any acts or omissions that are deemed unlawful, i.e., are contrary to the laws set out in statute by a legislative authority. Such behavior results in a victim, either through (1) direct injury or harm, or (2) damage or loss to their property.

Historical Background

Hans Asperger himself was the first to identify the risk of problematic behaviors when he described four children with core deficits in social interaction, communication, and inflexible patterns of behavior (Asperger 1944, trans. Frith 1991). Among them, three had been excluded from school as a result of aggressive behavior toward their peers. Asperger generalizes these behaviors as representing “autistic acts of malice,” which “appear to be calculated” (Asperger 1944, p. 77) and he adds that “with uncanny certainty, the children manage to do whatever is the most unpleasant or hurtful in a particular situation.” (Asperger 1944, p. 77) However, he does indicate that “because of their poorly developed emotionality they cannot sense how much they hurt others” (Asperger 1944, p. 77), an allusion to both their impairments of empathy and mentalizing (also referred to as “theory of mind”).

Current Knowledge

Unlawful behavior among individuals with autism spectrum disorders is an uncommon occurrence. Indeed, people with ASDs are probably more likely to be victims rather than perpetrators. However, a small number of people with ASDs will, unfortunately, find themselves in contact with the criminal justice system as defendants in connection with alleged criminal behavior, and it is therefore important for clinicians to understand patterns of such behaviors and the relevant etiological factors, as this will guide management and preventative strategies. Moreover, an awareness of the characteristics of ASDs among criminal justice system workers is vital in ensuring that the vulnerabilities of this group are not overlooked and that their rights as vulnerable witnesses or defendants are respected. In this entry, the literature concerning unlawful behavior among people with ASDs is discussed, and the clinical implications of this are expounded. In order to provide context, a discussion of criminological theory is first provided.

Much of the literature is concerned with individuals diagnosed with Asperger syndrome, although, based on current nosology, there is no reason to believe that the behaviors described are specific to Asperger’s vis-à-vis other higher functioning autism spectrum disorders. In contrast, it seems reasonable to believe that among those with ASDs and associated moderate to severe global intellectual disability (mental retardation in the DSM-IV), the risk of unlawful behavior is probably very small.

Overview of Theories of Criminal Behavior: Research with a criminological agenda has identified a number of factors that are associated with an increased vulnerability to offending, including both individual characteristics and factors in the environment. For example, individuals convicted for violent offenses have been shown to score relatively highly on extraversion and neuroticism, dimensions of personality first described by Eysenck. Moreover, two currently recognized personality disorders, antisocial personality disorder (ASPD) and psychopathy, both defined according to the presence of antisocial behaviors, are overrepresented in the criminal justice system and incarcerated populations (Fazel and Danesh 2002). Similarly, individuals with certain mental disorders also appear to have a raised vulnerability (Hodgins 2002). In particular, there is a modest but significant risk of criminal behavior by people with schizophrenia and major affective disorders. Several factors have been identified for both groups as mediating this risk, including associated antisocial behavior since childhood and drug and alcohol abuse. Moreover, among those with schizophrenia, there is some evidence that particular characteristics of the psychosis (such as, e.g., the presence of command hallucinations) may increase vulnerability to criminal behavior (Hodgins 2002).

Longitudinal studies have attempted to integrate environmental and individual factors that operate in a probabilistic way (Farrington 2002) and have identified factors related to family (such as large family size, poor housing, poor or inconsistent parenting, and a parent with a history of convictions), peer group (having friends who are delinquent), and the individual (low IQ and poor

school achievement, truancy, aggressive behavior, and hyperactivity-impulsivity-inattention) as accounting for significant variance in the risk of subsequent offending behavior.

Unfortunately, there are no studies as robust as these that specifically examine factors associated with criminal behavior among those with ASDs. However, there is no reason to believe that the factors identified by Farrington and colleagues will be any less important than in the general population. What is of particular interest, however, is whether factors related to the core autism phenotype increase the propensity to criminal behavior.

ASDs and Criminal Behavior: The Literature: A number of case studies and maximum security psychiatric hospital studies (“special hospitals” in the UK) have raised the awareness that some people with higher functioning ASDs come into contact with the criminal justice system as a result of alleged offending (summarized in Dein and Woodbury-Smith 2010). This has led to (1) speculation concerning whether there is an association between ASDs and offending, an issue that has remained unresolved in the absence of a prevalence study, and (2) an attempt to understand some of the factors associated with offending by the men and women described, an issue that has been beyond the scope of the methodology used.

Wing, in her seminal paper of 1981, “Asperger Syndrome: A Clinical Account,” described a small number of individuals who had a propensity for violent behavior (Wing 1981). One child, for example, with a special interest in chemistry, injured a colleague during the course of a “scientific” experiment. Wing also commented more specifically on how a lack of social understanding could lead to contact with the criminal justice system: “he has no idea of how to indicate his interest and attract a partner in a socially acceptable fashion. If he has a strong sex drive, he may approach or touch or kiss a stranger, or someone much older or younger than himself and as a consequence find himself in trouble with the police” (Wing 1981, p. 116).

Tantam (1988) also studied adults with a lifelong history of social isolation and eccentricity (Tantam 1988), many of whom also met the

diagnostic criteria for AS. Among the 60 cases, forensic information was available on 54 of whom 24 (44%) were reported to have engaged in unlawful behaviors but only 12 (22%) of whom were charged. Fourteen of the 54 had committed offenses punishable by imprisonment, including criminal damage (4), assault (3), arson (3), indecent exposure (3), and attempted rape (1). Clearly, without a comparison group, it is not possible to say whether the prevalence of offending in this group was high. It is also unclear which of those exhibiting problematic behavior met the diagnostic criteria for AS.

In a similar manner, Wolff described a group of children who were socially isolated from their peers (Wolff 2000). Crucially, hers was a longitudinal study, allowing outcomes into adulthood to be examined. In considering the schizoid boys, there was no evidence of any raised prevalence of delinquency, measured by self-report methodology, compared to a control group. However, the self-report results of the schizoid girls indicated that they had rates of delinquency similar to the boys and higher than the control girls. Wolff also approached the Scottish Criminal Records Office to undertake a search of official convictions for the 109 schizoid boys and 32 schizoid girls and the matched controls. Among the population control group, 22% of men and 5% of women had convictions, whereas in contrast 32% of the schizoid men and 34.5% of the schizoid women had convictions. When compared with the control sample, recruited from a psychiatric clinic, the rates for schizoid men were comparable (34.5% of control men with a conviction), whereas the rates for schizoid women were still significantly higher (15.5% of control women with a conviction). Of note is that there was no difference in the nature of offenses between the schizoid and control groups, and none had committed a particularly violent offense. However, 3 years after this survey was undertaken, one of the schizoid men had entered the home of a housewife by posing as a priest, attacked her with a poker, and sexually assaulted her (Wolff 2000).

The numerous case studies published since have described a number of different unlawful behaviors, and it is fair to say that no pattern

concerning type of offense has emerged. While a few have described more serious offenses, such as murder, this is the exception rather than the rule. What does seem true, as discussed subsequently, is that most transgressions occur as a result of social naïveté, a rigid interpretation of rules or interpersonal misunderstanding along with the desire for relationships with others. As a result, people with AS may be arrested following altercations with others, while offenses may take the form of harassment or more seriously sexual assault.

Importantly, being case studies, these publications say nothing about the prevalence of criminal behavior, which remains unknown. While two special hospital studies in the UK have described an overrepresentation of ASDs in such facilities, community studies have indicated that the prevalence is probably no higher than in the general population (Woodbury-Smith et al. 2006). However, what is most interesting regarding these case studies is the insight they provide as to the possible etiological factors that led to the problematic behaviors in each case, as is described in the next section.

The Factors Associated with Offending Among Individuals with ASDs: People with ASDs are generally law-abiding citizens. Indeed, the rigidity of thought that is characteristic of the disorder may result in a very strict adherence to rules. For example, a person with an ASD may be horrified by transgressions as minor as traveling marginally over the speed limit. Strikingly, however, even this intense adherence to rules may result in inadvertent contact with the criminal justice system. By way of a trivial example, imagine the person with AS who confronts someone for talking in the library. He may either risk being assaulted himself, or if his annoyance escalates, he may push the person involved, thereby exposing himself to the risk of charges of assault. Similar infringements have been described in the literature.

One commonly described mediator of problematic behaviors is the pursuit of a circumscribed interest. Such interests form a core part of the phenotype, particularly among those who are higher functioning, and may take different

forms. Often, they involve the acquisition of knowledge, but other forms include collecting and the pursuit of an activity such as a sport or hobby. Regarding the latter, it is their intensity that distinguishes them from the pursuit of such activities among their typically developed peers. In other situations, some people with AS may become particularly interested in certain figures, either from history or present times.

In the research literature, a number of case studies have been described in which people with ASDs have apparently engaged in unlawful behaviors during the pursuit of a circumscribed interest (discussed in Woodbury-Smith et al. 2010). These include theft and burglary in the context of a circumscribed interest, as well as assault. Woodbury-Smith et al. (2010) systematically studied a sample of 21 intellectually able offenders with ASDs, among whom a putative relationship could be established between their index offense and circumscribed interest in six. In addition, when the interests of this group were compared with 23 matched adults with ASDs with no history of offending, interests of a violent nature were overrepresented in the former group.

While offending in the context of a circumscribed interest has formed the focus of several case studies, in day-to-day terms, most transgressions are likely to occur in the setting of social misunderstandings. People with ASDs may be blunt, are likely to speak their mind, and may come across as rude. This may result in offense being taken by another person, and an altercation may follow. In this current discussion, this is particularly pertinent when someone with an ASD is in court as a witness or accused and may come across as arrogant as a result of their communicative bluntness. More generally speaking, people with ASDs may fail to appreciate situations from another's point of view or may be unable to read others' nonverbal cues.

Unlawful transgressions as a result of the social impairment are, perhaps, most likely to occur among isolated young adults who wish for relationships with others but do not necessarily know how to go about achieving such a relationship. They may, therefore, make clumsy or

inappropriate approaches. Moreover, this may be coupled with an inability to read the fearful and/or angry nonverbal cues of (disinterested) others. Under normal situations, these cues would act in an inhibitory manner, but without such mechanisms, the person with AS may continue their attempts at engagement. There is little doubt that in certain situations, this can lead to more serious transgressions. This mechanism may go some way to explain the cases of harassment and/or stalking described in the literature by people with ASDs. Similarly, some cases of inappropriate sexual behavior, including indecent exposure and sexual assault, may be extreme cases of the same mechanism.

There is certainly some evidence to suggest that social transgressions may be associated with an inability to read nonverbal cues and, in particular, the identification of expressions of fear in others (Woodbury-Smith et al. 2005). Interestingly, Woodbury-Smith et al. (2005) also found that the offenders with ASD were significantly better than their non-offending ASD counterparts in theory of mind. This suggests that the relationship between ASDs and unlawful behavior is more complicated, particularly as such neuropsychological profile has also been found among those labeled as psychopaths. It is possible that a small group of people with ASDs may be predisposed to criminality by way of a “double hit,” whereby an additional disorder exists side by side with the ASD as a result of the individual being exposed to both sets of risk factors (Rogers et al. 2006). As a model, this requires further explanation, but it does offer insight that could guide management.

These same mechanisms may also explain some of the cases of aggression that have been described in the literature, including those described by Asperger himself. Asperger believed that such behaviors were indicative of “autistic acts of malice,” characterized by “calculated behavior” (Asperger 1944, op. cit., p. 77) which results in behavior that is the most “unpleasant or hurtful in a particular situation” (Asperger 1944, p. 77). However, an important distinction needs to be made between acts that are purposeful, and

carried out with the intent of upsetting or hurting another person, and acts that are carried out with little understanding of the impact they may have on the other person. Although Asperger used the word “malice,” suggesting a purposeful attempt to hurt emotionally, he is quick to point out that the person with the syndrome he describes “cannot sense how much they hurt others” (Asperger 1944, p. 77). The implication, therefore, is that aggression and other transgressive and unlawful behaviors resulting in a victim may occur without a full appreciation of the distress provoked.

Asperger Syndrome and Criminal Responsibility: A person is deemed not criminally responsible if he lacks the capacity to appreciate the nature and quality of their action or know that their act was wrong. The interpretation of this piece of statute has been the focus of debate and disagreement, particularly with relation to the word “wrong.” In narrow terms, “wrong” may be construed as “breaking the law.” However, in broad terms, it includes knowing that something is both “morally” and “legally” wrong and, in this sense, requires the person to have a knowledge of the law of their jurisdiction but also to have a moral code by which certain (amoral) behaviors are inhibited by them (i.e., having the ability at a cognitive level to empathize with others). In this broader sense, therefore, it might be argued that certain people with ASDs lack the capacity for criminal responsibility. There is no clear guidance on this matter, however (see Fine and Kennett 2004 for a discussion of mental responsibility in connection with psychopathy).

Management Implications: Recognizing that a small number of people with ASDs will come into contact with the criminal justice system, it is important for the key people in the legal arena to be aware of the diagnosis, because of the implications it may have for fitness to plead and stand trial, and criminal responsibility (Dein and Woodbury-Smith 2010). Moreover, people with ASDs may be vulnerable (e.g., suggestible) during the police interview, and their behavior in the courtroom may bias a jury if they do not know the person has the diagnosis. The rehabilitation needs of this group also needs consideration. In the

absence of clear, evidence-based guidelines, assessment and management demand pragmatism (Clare and Woodbury-Smith 2009). However, certain therapeutic practices used for children with ASDs, such as social skills training, may be usefully translated into the adult population to teach a wider set of social rules. Moreover, techniques such as cognitive-behavioral strategies, role playing, and computer-based emotional simulation may go some way to teach “moral capacity,” although the effectiveness of these measures for this purpose has not been tested. Similarly, strategies to reduce problematic circumscribed interests, such as CBT, are not well founded in evidence, although in practical terms, reduction of boredom and the introduction of structure and positive life experiences are likely to help.

Future Directions

In summary, there is still much unknown about the true extent of unlawful behavior among people with ASDs as well as relevant risk and protective factors. Nonetheless, what does seem reasonable to conclude is that a small yet significant number of people with ASDs, particularly those who are functioning within (or just below) the normal range of intelligence, may come into contact with the criminal justice system as a result of alleged unlawful behavior. These infringements are on the whole relatively minor. Their importance lies in the fact that in many cases, a relationship between the behavior and the core clinical and neuropsychological phenotype of the disorder can be hypothesized. Much research is still required, but in the meantime, awareness of the diagnosis among the mental health, police, and legal professions is vital to ensure that people with ASDs are given the best opportunities of rehabilitation, and their vulnerabilities are adequately recognized.

The visual cortex consists of those parts of the brain associated with processing the visual sensory input. Anatomically, these regions correspond most closely to the occipital lobe. Functionally, the visual cortex consists of multiple retinotopically organized maps, i.e., spatially organized by the way that visual input is received on the retina.

Definition

Visual narrative comprehension refers to the access of semantic information in a story presented as pictures, such as a comic or graphic novel. Like language, sequential image comprehension is characterized by two processing streams. First, readers must integrate semantic information across images and update a mental model of the unfolding scene or story (Magliano and Zacks 2011; Zwaan and Radvansky 1998). Second, a “narrative grammar” organizes and constrains this semantic information with categorical roles embedded in hierarchic constituent structures, similar to the syntactic structure of sentences (Cohn 2013; Cohn et al. 2012). According to the theory of visual narrative grammar (Cohn 2013, 2019), these categorical roles include Establishers (panels that set up an interaction or event), Initials (panels which initiate the event in the narrative arc), Peaks (panels which depict the height or climax of the narrative arc), and Releases (panels which resolve the event or interaction). While these categories are similar to traditional notions of narrative (e.g., set up, rising action, climax, resolution), such roles are not

descriptors of meaning itself but are determined through interactions between the bottom-up semantic content in images and the top-down sequential context (Cohn 2013, 2014). That is, the same panel can serve as a peak or an initial depending on its placement in the visual narrative sequence and its role in the narrative. Just as meaningful information in a sentence can be independent of its syntax, meaningful information in a story is independent from the narrative structure ordering that meaning (e.g., Brewer 1985; Cohn 2013). Thus, this narrative grammar is separate from semantics, just as syntactic structure is separate from – yet interfaced with – meaning in sentences (Cohn et al. 2012).

Visual narrative comprehension is commonly assessed behaviorally by asking participants to arrange randomly presented pictures in a temporal order to construct a coherent story. The produced story is scored as either “correct,” if the pictures are ordered in the way expected by the test designers, or “incorrect,” if the pictures are placed in a different order. Such tasks are included in many intelligence tests such as the Wechsler intelligence scales, including the Wechsler Intelligence Scale for Children (WISC; Wechsler 2014) and the Wechsler Adult Intelligence Scale (WAIS; Wechsler 2008), which both include a picture arrangement subsection.

Comprehension can also be assessed using neuroimaging techniques such as electroencephalography (EEG), which measures the electrical activity of the brain via electrodes placed on the scalp. Brain responses that are time-locked to the onset of a specific stimulus are known as event-related potentials (ERPs) and reflect various stages of cognitive processing of that stimulus. The *N400* component of the ERP, a negative-going deflection peaking approximately 400 milliseconds (ms) after stimulus presentation, has been established as an index of semantic processing (Kutas and Federmeier 2011). In typically developing individuals, *N400* amplitude is reduced for semantically congruent stimuli (e.g., contextually congruent words or comic panels at the end of a narrative) relative to semantically incongruent stimuli (e.g., contextually incongruent words or

comic panels; Kutas and Federmeier 2011; Kutas and Hillyard 1980; Lau et al. 2008). The amplitude difference between congruent and incongruent conditions is often referred to as the *N400* effect and is taken to reflect semantic understanding, with smaller *N400* effects representative of poorer comprehension.

While it is well-documented that individuals with ASD show impairments in understanding linguistic narratives (Braeutigam et al. 2008; Dunn and Bates 2005; Dunn et al. 1999; Jolliffe and Baron-Cohen 2000; Kaland et al. 2007; Mason et al. 2008; McCleery et al. 2010; Nuske and Bavin 2011; Pijnacker et al. 2010; Strandburg et al. 1993), fewer studies have investigated comprehension of visual narratives. Those that have suggest that narrative comprehension impairments persist even for nonlinguistic modalities. For instance, children with ASD showed impairments in picture arrangement for stories requiring ToM (Baron-Cohen et al. 1986). Children with ASD have also shown deficits compared to TD children in inferring missing panels from visual event sequences (Davis et al. 2007) and predicting the final image of event sequences (Zalla et al. 2010). Electrophysiological studies have also documented impairments in visual narrative comprehension in individuals with ASD, with this population showing smaller *N400* effects compared to typically developing individuals for incongruent panels at the end of a visual narrative sequence (Coderre et al. 2018).

It is commonly assumed in the autism field that including visual supports when reading will alleviate processing difficulties, as they play to the “visual strengths” of these individuals (Coderre 2019). However, the emerging evidence documenting impairments in visual narrative comprehension in individuals with ASD may point to domain-general impairments in narrative comprehension that persist even for visual modalities. Visual narrative comprehension relies on many of the same domain-general cognitive skills as linguistic narrative comprehension, such as executive control, working memory, theory of mind, and inference generation (Bower and Morrow 1990; Cohn 2014; Cohn and Kutas

2015; Cohn and Wittenberg 2016; Gernsbacher 1997; Linderholm et al. 2004; Magliano et al. 2016; McCloud 1993). Because visual and linguistic narrative comprehension draw on similar cognitive skills, impairments in these underlying skills may translate into impaired comprehension for both visual and linguistic modalities. Further work is needed to fully understand the factors that play into narrative comprehension impairments in individuals with ASD.

Visual processing in autism: the lows and highs

Historical Background

Atypical behavioral performance, at multiple levels of visual processing, has been observed in individuals with autism, and unsurprisingly, changes to the neural mechanisms subserving these visual behaviors have often been documented, as well. Perhaps, most intriguing is the finding that, while some visual behaviors appear to be compromised in individuals with autism, relative to typical individuals, others appear to be superior relative to their typical counterparts, and *enhanced perceptual functioning* (Motttron et al. 2006) is increasingly considered part of the autism phenotype. Here, an overview of visual processing in autism from lower through mid- to higher levels of processing is presented. Recent findings concerning the psychological and neural mechanisms mediating these atypicalities as well as some ongoing controversies and debates are summarized; for example, the review considers whether atypicalities in earlier levels potentially have a snowball or cascaded effect such that the observed differences in the computation and representation of visual information in higher-order levels in the autism population might arise from these lower-level perturbations, and there is a call for additional investigations to address the outstanding issues.

It is important to note that alterations in visual processing in autism are many and varied, and reviewing all of these is well beyond the scope of this summary. The focus, then, is mostly restricted to examining the functions of the

cortical ventral visual pathway (although dorsal cortical function will be briefly considered) in individuals with autism. Thus, there is no discussion of optometric functions in autism although there is a high prevalence of strabismus, refractive error, altered ocular alignment, and difficulty with voluntary pursuit eye movements, among other visual symptoms; for a recent short review, see Simmons et al. (2009). It is also the case that there are cognitive or higher-order visual functions that are adversely affected in autism, including, among others, atypical saccadic behavior, alterations in attentional function, unusual socially directed pointing, difficulties with interpretation of gestures, unusual eye contact, difficulty with the interpretation of facial expressions, imitation, and difficulty following the gaze of others and engaging joint attention. This review does not elaborate on these higher-order behaviors in this section although some of these symptoms are critical to the phenotype of autism and are included in the Autism Diagnostic Observation Schedule (ADOS) (Lord et al. 2000).

Current Knowledge

Lower-Level Vision: Striate and Extrastriate Cortex

Many studies of lower-level vision in autism have concluded that elementary visuo-perceptual skills are, at least, preserved or possibly even enhanced in individuals with autism (Ashwin et al. 2009; Mottron et al. 2006, 2009; Soulières et al. 2009), relative to typical controls. Recent studies have demonstrated sensory hypersensitivity with better detection thresholds in vision in individuals with autism, compared with their typical counterparts (Baron-Cohen et al. 2009), and have documented excellent attention to detail in these same individuals (for more on this topic, also see later sections), although the latter may be a direct product of the sensory hypersensitivity per se (Joseph et al. 2009; Mottron and Burack 2001). Of interest, a recent report by Ashwin et al. (2009) described significantly better visual acuity (20:7) in adults with autism compared with control subjects (20:13), an acuity so superior that it lies in

the range reported for birds of prey (although note that this may not hold generically; Keita et al. 2010). However, previous studies with children with ASDs found unexceptional acuity and, indeed, reported that many of the children actually exhibited inferior acuity (Emigh and Procyk 1992). Further investigation into the acuity characteristics of individuals with autism is clearly necessary. See also (Dakin and Frith 2005; Simmons et al. 2009) for further discussion of early sensory processing skills in autism. Support for the reported enhancement of early perception in autism is also gleaned from experiments which show that whereas typical controls' peripheral target perception is adversely affected by the presence of flankers (stimuli in the spatial surround), individuals with autism may have enhanced focus and, thus, be relatively immune to this crowding effect (Baldassi et al. 2009). Finally, neuroimaging studies of adults with autism suggest that the retinotopic organization in early visual cortex may be comparable to that of typical adults, with typical topographic representation of foveal and peripheral fields in early visual cortex (Hadjikhani et al. 2004a).

One fairly consistent finding of atypical lower-level visual processing in autism concerns the extraction or representation of fundamental aspects of incoming percepts. For example, atypicalities in spatial frequency processing in autism have been documented in several recent studies. One such study compared early visual evoked potentials (VEPs) elicited to sine-wave gratings of different spatial frequencies (Jemel et al. 2010) in autism and control participants. Whereas VEP contrast responses to low- and high-spatial-frequency gratings did not differ between the groups, in the autism group, early VEPs to mid-spatial-frequency gratings were similar to those obtained in response to high-spatial-frequency gratings. These data indicate an alteration in the functional segregation or selectivity of early visual channels, especially those responsible for processing mid- and high-frequency spatial scales in autism. Alterations in VEPs elicited by Gabor patches of varying spatial frequency in individuals with autism have also been documented by Milne et al. (2009). They found that the onset of

even a simple visual stimulus perturbs the activity of a widespread network including sensory, parietal, and limbic areas and that the observed reduction in spectral power across multiple regions may reflect a reduction in the synchrony and size of the neural networks recruited during perceptual processing.

This reported alteration in neural integration may also account for the relative difficulty these individuals experience in identifying complex texture-defined gratings (Bertone et al. 2003, 2005). Whereas these individuals are more accurate at detecting the orientation of first-order gratings (simple, luminance-defined) than controls, they are less accurate at identifying the second-order gratings. Bertone et al. (2005) hypothesize that because simple visual stimuli can be processed in a single brain area (typically V1), perception of first-order gratings may be unaffected. Complex stimuli, on the other hand, are processed in multiple brain areas, and the reduced efficiency of neurointegrative mechanisms in autism (see below for further discussion of the topic of connectivity) and perhaps weak central coherence (Shah and Frith 1993) may explain the reduced ability to perceive more complex stimuli.

Consistent with this hypothesis, VEPs recorded while autism participants observed orientation-based texture and contour stimuli forming coherent global patterns revealed the absence of certain harmonics, characteristic of global form processing, and even when harmonics could be elicited in the autism group, the amount of organization required to do so was higher than in the nonautism control group (Pei et al. 2009; Vandenbroucke et al. 2008). Together, these findings indicate that early aspects of high spatial frequency and form extraction are atypical in adults with autism, especially as stimuli become more complex and multiple brain regions are required.

As alluded to above, these findings of atypical lower-level visual processing can be accommodated by a view that argues that vision in autism is mediated by a system with increased local connectivity and a dysfunction of long-range intracortical connections, which are necessary for integrative higher-order visual processes.

Specifically, increased local connectivity, particularly in posterior, sensory parts of the cerebral cortex, may account for the unusual sensory “magnification” strengths and enhanced perception of local features as well as the increased focus (and immunity to distracters) observed in some cases of autism (Belmonte et al. 2004). At the same time, there is reduced neurointegration and so perception of stimuli that are complex or necessarily engage a range of cortical regions is adversely affected.

The altered local lateral connectivity in autism might originate from an imbalance in excitatory/inhibitory neural signaling, resulting in changes regarding elementary feature extraction. Predictably, then, as outlined by accounts of enhanced perceptual functioning, there is increased physiological engagement of occipital cortex and occipitoparietal areas typically involved in primary perceptual functions, coupled with reduced frontal activity (Mottron et al. 2006; Samson et al. 2011) that may explain the autistic perceptual endophenotype (Mottron et al. 2009, 2006).

Mid-level Vision: Ventral Occipitotemporal Cortex

Perceptual Grouping

In addition to the atypicalities observed in early parts of the visual system, there are also atypicalities noted in processes requiring perceptual organization. For example, individuals with autism are able to identify fine stimulus features in spatial tasks like block design (Jolliffe and Baron-Cohen 1997; Shah and Frith 1983) and are notoriously faster and more accurate at finding embedded information, such as in the Embedded Figures Task (Happé and Frith 2006). This profile is also consistent with the notion that brain activity in participants with autism during such tasks is higher bilaterally in occipital cortex and in the cerebellum, as well as in the left posterior parietal cortex, compared to typical controls, but it is lower in frontal cortex (Lee et al. 2007; Manjaly et al. 2007; Ring et al. 1999). Interestingly, even when visual behavioral performance is equated across the control and autism group in an embedded figures-type task, the autism individuals

continue to show heightened activation in the posterior parietal cortex and occipital areas and less activation in the left dorsolateral prefrontal and inferior parietal areas. Furthermore, there is decreased functional connectivity between higher-order working memory/executive areas and visuospatial regions in the autism participants (Damarla et al. 2010; Schipul et al. 2011), reflecting the difficulty with long-range connectivity and neural integration discussed above (for a similar recent result, see Liu et al. 2011).

Several studies have reported superior abilities to detect local targets in visual search tasks in autism (Joseph et al. 2009; Plaisted et al. 1999), which is associated with higher occipital cortex activity (Keehn et al. 2008). Individuals with autism are also better able to ignore the influence of increasing numbers of distracters during visual search (O’Riordan and Plaisted 2001), and they outperform controls in change blindness tasks, detecting more errors/changes in visual scenes (Smith and Milne 2009; see also discussion of crowding phenomenon above). These superior visual search skills may come at a cost, however. Individuals with autism are apparently limited in their ability to derive organized wholes from perceptual parts, which is critical for many aspects of higher-order visual processing such as object recognition. This integration difficulty has been linked to limited use of gestalt grouping heuristics (Brosnan et al. 2004; Farran and Brosnan 2011), the failure to process interelement relationships (Behrmann et al. 2006; for similar results in children and adolescents with autism, see Scherf et al. 2008), and/or the failure to consider the entire visual context (Happé and Frith 2006; Liu et al. 2011). Yet others have suggested that the problem lies in limited abilities to integrate local elements specifically into a coherent global shape (Plaisted et al. 1999; Rinehart et al. 2000; Wang et al. 2007). Note, however, that there are some studies that report typical processing of both the global and local information in hierarchical visual stimuli (Iarocci et al. 2006; Mottron et al. 2003; Ozonoff et al. 1994; Plaisted et al. 2006). Similarly, a recent study reports increased sensitivity to mirror symmetry in autism, again indicative of parallel access to both local and global

information and the possibility that individuals with autism may extract from noisy environments genuine regularities, which elude nonautistic observers (Perreault et al. 2011). Thus, whether there is undue reliance on local elements and/or difficulty in achieving a global percept (or possibly neither) in autism continues to be a source of much debate in the field. Whether these different profiles are indicative of heterogeneity in the population per se or whether the different results emerge from the adoption of different paradigms and analyses remains to be determined.

Motion Perception

As with perceptual grouping, detecting coherent motion involves the integration of multiple local elements, and there is also significant controversy about whether observers with ASD differ from typical observers in their visual analyses of movement. Some initial studies suggested that observers with autism experience marked deficits in their visual sensitivity to coherent motion in random dot displays but not to point-light displays of human motion (Milne et al. 2002; Spencer et al. 2000). More recent evidence suggests exactly the opposite: that observers with autism do not differ from typical observers in their visual sensitivity to coherent motion in random dot displays but do differ from typical observers in their visual sensitivity to human motion (for review of this literature, see Kaiser and Shiffrar 2009). For example, one recent study that directly compared human motion perception versus object motion (tractor motion) revealed that whereas typical observers are more sensitive to the former than the latter, observers with autism showed equivalent levels of sensitivity to both (Kaiser et al. 2010). The explanation offered for this latter result is that the visual systems of individuals with autism may not be tuned for the detection of socially relevant information such as the presence of another person. An explanation offered for some of these findings is that autism observers are likely able to detect coherent movement (Atkinson 2009; Blake et al. 2003) but that, during development, the posterior superior temporal sulcus might not be increasingly tuned to differentiate human motion from object motion in autism (Pelphrey and Carter 2008).

In sum, the studies examining mid-level vision in autism usually reveal atypicalities in perceptual grouping and in motion perception, although the particular profile of the findings is not perfectly consistent across every study. Taken together, however, the weight of the evidence favors atypicalities in mid-level vision in autism, and these atypicalities appear to hold across children, adolescents, and adults with autism. It has been suggested that, from a developmental perspective, the atypical emergence of these perceptual organizational processes may contribute directly to disruptions in the processing of visually presented objects, which may, in turn, fundamentally influence the development of major aspects of the social and emotional deficits characteristic of autism (for recent discussion of social deficit and complexity of this deficit; see New et al. 2010). Additionally, the reduction of visual sensitivity to human movements could compromise important social behaviors including, for example, gesture comprehension, and in this way, foundational visual processes could adversely impact not only higher-order visual processes but also could have direct impact on social behaviors, too.

Higher-Level Vision: Beyond the Calcarine Sulcus

Just as atypicalities in early sensory vision in autism impact mid-level grouping and integration abilities, so too do atypicalities in mid-level vision have direct consequences for higher-level visual skills. Moreover, this cascade may disproportionately affect some types of stimuli, such as faces, in which the input similarity is especially high and the featural differences themselves do not suffice to support differentiation of individual exemplars (Boucher and Lewis 1992; Davies et al. 1994; Hobson et al. 1988; Joseph and Tanaka 2003; Klin et al. 2002; Lahaie et al. 2006). Given that all faces have two eyes, a nose, and a mouth and that these all share the same first-order configuration (eyes above nose above mouth), it has been argued that faces, to a greater degree than any other object type, rely on the ability to derive a second-order or holistic representation, the very ability that seems unduly taxed in autism.

To evaluate the relation between the local visual processing bias and impaired face and object processing skills in autism, Behrmann et al. (2006) tested adults with autism, whom we already knew evinced a local bias across two very different perceptual organization tasks, in several same/different judgments tasks with faces, common and novel objects. Not only were the adults with autism slower than typical adults when making the same/different similarity judgments, but more relevant for the current discussion, they were disproportionately slower in their similarity judgments as the stimuli became increasingly similar. These results reveal the disproportionate difficulty in the more demanding tasks that require perceptual binding of the elemental features, and it is in these cases that featural distinctions do not suffice, and integration of the features into higher-order configurations become essential. Additionally, performance in these more taxing face and novel object discrimination tasks was significantly correlated with the local bias on the global/local task. Although correlation is not causation, the relationship between performance in face and object processing and the local bias appears clear in the autistic adult individuals and is highly suggestive of an association between them.

The atypicality in face processing has also been associated, in many studies, with altered neural activation in higher-order regions of visual cortex, most notably the fusiform gyrus. Many studies have found reduced BOLD activation in this region for faces compared with other visual classes (for a few examples, see Corbett et al. 2009; Critchley et al. 2000; Dalton et al. 2005; Hubl et al. 2003; Pierce et al. 2001; Schultz et al. 2000; Wang et al. 2004) although a few studies have failed to replicate this finding (Hadjikhani et al. 2004a, b; Pierce et al. 2004). The analysis of the cortical substrate of face perception has focused on the preeminent FFA but also on a more widely distributed network of brain areas involved in face processing, and, at least in one study, hypoactivation has been identified more broadly in regions including the right amygdala, inferior frontal cortex, superior temporal sulcus,

and face-related somatosensory and premotor cortex (Hadjikhani et al. 2007).

In another study using naturalistic, real-time movies of unfamiliar faces, buildings, and navigation through open fields, the cortical activation profile from the typical group largely replicated the standard findings with extensive activation for faces and objects and activation (albeit less extensive) for building/scene-related displays (Humphreys et al. 2008). In contrast, there was a clear reduction in face-related activity throughout the ventral visual pathway in the autism group. Interestingly, and consistent with those studies showing enhancement in object-related activation (Pierce et al. 2004), there was more extensive object-related activity in lateral occipital cortex for the autism than comparison group bilaterally.

Adolescents with autism, under the same experimental conditions, failed to show consistent face-selective activation in classical face regions, revealing that the alteration in functional topography of face-related cortex in autism is present early on. Additionally, for those few adolescents with autism who did exhibit face-selective activation, face-selective cortex was located in traditionally object-related regions, supporting the hypothesis that perceptual processing of faces in autism may be more akin to the perceptual processing of common objects in typically developing individuals. Such alterations could result from direct pathology to regions within the face-processing network, like the fusiform gyrus (Hadjikhani et al. 2007), and/or to the structural and functional connections between such regions (Thomas et al. 2011). Also, alterations in the visual experiences that individuals with autism have with faces as a result of social aversion and/or excessive focus on features may configure these regions in the face-processing network atypically (Grelotti et al. 2005; Hadjikhani et al. 2004b).

Taken together, there is substantial behavioral and neuroimaging evidence to suggest that individuals with autism exhibit heightened sensitivity to elemental features in visual objects, which may interfere with their ability to perceptual

group these elements to perceive the holistic gestalt of the image. This profile of atypical visual processing may be especially detrimental to face processing, which relies heavily on holistic processing or relational representation of elemental features. In contrast, it may boost processing of common objects, which can be easily discriminated based on differences in elemental features.

Finally, a recent meta-analysis based on 26 published functional magnetic resonance imaging (fMRI) studies of face, object, and word visual processing in adults with autism has indicated that individuals with autism exhibit generally stronger engagement of visual processing regions, including striate and extrastriate regions, and parietal regions, including the precuneus and intraparietal sulcus, than controls (Samson et al. 2011). More controversially, this review states that these results do not support the claim that there is *hypoactivation* in face-selective regions in autism although, consistent with previous studies (e.g., Scherf et al. 2010), they do suggest that the locus of fusiform face-selective activation may be atypical in autism and located in regions that are object-selective in controls. Suffice it to say, much remains to be done to characterize the cortical profile in individuals with autism engaged in high-level visual processing tasks, and the correspondence between the brain activity and behavior remains to be clarified, too.

Future Directions

Conclusions

The unusual and varied visual processing skills in autism reviewed here span early to late stages of the visual processing stream. Disparities between individuals with autism and typical individuals are observed in tasks engaging lower-level visual features, and atypicalities are observed under conditions engaging mid- and higher-level visual stages, too. This widespread set of altered visual behaviors and their neural correlate is not easily accounted for by views that argue for a primary social deficit in autism (Scherf et al. 2008), and

thus, there is increasing recognition of the rather pervasive perceptual deficit, too. For example, Batty et al. (2011) showed that, when verbal age was matched across a group of children with autism and typical controls, their ERP profiles, recorded during an implicit emotional recognition task, differed only in the amplitude of the early P1 component. This led the authors to suggest that the emotional and facial processing difficulties in autism could start from atypicalities in visual perceptual processes involving rapid feedback to primary visual areas and have subsequent impact on holistic processing. Whether the social and perceptual deficits are independent or interdependent remains to be determined. While some have suggested that the atypical perceptual processing in children with autism is a secondary effect of profound social-communicative deficits that alter the nature of the child's early environmental inputs and disturb the normal course of brain growth and organization, the perceptual difficulties, themselves, may contribute to the alterations in social behavior.

As abundantly evident, many key issues remain to be addressed including broad questions such as what neurobiological events trigger the unusual psychological and neural processes that underlie the altered perceptual profile in autism. More specific questions such as the integrity of particular brain areas, such as the fusiform face area in autism, also remain to be determined. Characterizing the atypical visual behaviors in fine-grained detail and their underlying neural correlates is critical, too, and although individuals with autism might evince some enhanced visual skills, these are not necessarily advantageous, and the highs and lows of their visual experience remain to be fully characterized. Finally, understanding the impact of these atypical skills on daily living and the potential for intervention remain at the top of the list of issues to be addressed.

Definition

Individuals with ASD present with difficulties in understanding and maintaining social interactions, and impaired emotional face processing is a crucial feature of ASD that might be responsible for impairments in the social cognition domain. As acknowledged by a large literature, children and adults with ASD have difficulties in interpreting and categorizing emotional faces, which might be related to avoidance of the eye region of the face. For example, those with ASD

might avoid direct gaze from others and thus not respond in an adapted manner to the social content of others' facial expressions (e.g., not returning a smile). Nevertheless, considerable heterogeneity characterizes both behavioural and neuroimaging studies (Jemel et al. 2006), showing that different results can be found depending on the participants' demographics (e.g., age, severity of autism, language, and/or intellectual level) or on experimental design choices.

To investigate emotional face processing in experimental settings, individuals are often asked to recognize emotions explicitly by detecting or categorizing specific expressions, thus orienting the subject's attention toward the emotional content (top-down process). In everyday life, however, the emotional content of faces is often implicitly processed outside of conscious awareness, allowing one to both understand and communicate intentions with others rapidly in an automatic way (bottom-up process). To study implicit emotional face processing, instructions are usually given to the participants to recognize a face feature other than the emotion itself (e.g., gender) or to recognize another object or stimulus feature while the facial emotions are irrelevant. This allows the researcher to record behavioural responses to the task, therefore confirming task compliance, and at the same time investigate at the brain level implicit or incidental emotional face processing.

Studies have shown that while explicit emotional processing might be intact in some individuals with ASD, atypicalities can be found during implicit tasks (see Kana et al. 2016). It has been suggested that explicit instructions could help people with ASD process the social world more efficiently, while the automaticity of implicit emotion processing would not allow the compensatory mechanisms and may contribute to difficulties observed in ASD (Kana et al. 2016). Although individuals with ASD might explicitly recognize emotional facial expressions as well as typical peers, some studies have shown atypical brain activity, suggesting that individuals with ASD recruit different brain regions to recognize emotions accurately (Wong et al. 2008).

Together with difficulties in the communication and social domains, atypical sensory processing, including hypo- and hyper-responsiveness, is now considered an important diagnostic feature of ASD. In the visual modality, this presents via clinical signs such as light-gazing, shaking fingers in front of the eyes, pressing on the eyes, or lateral glances but also via an increasing literature showing atypical patterns of brain responses to visual stimuli (see Simmons et al. 2009). Given both the sensory and social difficulties in autism, it is crucial to consider faces, not only as important social stimuli but also as visual stimuli.

For instance, to better understand emotional face atypicalities, it is essential to study brain responses from the earliest visual stages, including those preceding face-sensitive responses. To this end, several neuroimaging techniques can be used, such as MEG/EEG or fMRI, to characterize the temporal and/or spatial nature of the brain activity and highlight possible group differences. The N170, a component recorded via the EEG over the temporal regions and reflecting the neural processing of face stimuli, is often abnormal in individuals with ASD. Importantly, the P100 component preceding the N170 and recorded over the occipital region has also been found atypical in children and adults with ASD, suggesting that the earlier stages of visual processing are also affected with face stimuli. In a similar vein, in addition to atypical activation of regions implicated in the processing of faces (e.g., fusiform gyri), abnormal patterns of activation in the occipital cortex have been reported by source analyses (MEG/EEG) (Kovarski et al. 2019; Wong et al. 2008) and fMRI studies.

Taken together, these investigations highlight that brain processing differences exist from the first stages of visual processing, occurring early in time and likely affecting successively higher-level processing. Thus, early visual disturbances appear to be affected in individuals with ASD and can have detrimental consequences on the processing of emotional faces. As the nature of the task is known to modulate brain activity,

using implicit emotional tasks allows the identification of these visual disturbances independently of the frontoparietal projections to the visual cortex, which are modulated by explicit attention to emotions (Vuilleumier and Driver 2007).

Visual Scanning

Definition

Visual scanning refers to the ocular strategies employed for exploring various classes of visual stimuli including faces, objects, and scenery. Scanning patterns reflect the viewer's strategy for acquiring visual information. Therefore, visual scanning precedes visual information processing. Ocular strategies, movements and fixations measured with eye-tracking technology, are the focus of this section.

Historical Background

The suggestion that people with autism view the world differently than neurotypical individuals is not new. An early study of facial recognition indicated that children with autism were better able to judge facial identity than controls using only the eye or mouth region rather than images of the whole face. Younger children showed particularly heavy reliance on the mouth region (Langdell 1978). The observation that children with ASD use different information than their typically developing peers suggests the likelihood that they also explore faces differently. An investigation of looking targets during a solitary play task indicated that toddlers with ASD looked less to people and more to objects, demonstrated fewer shifts of attention toward people and more shifts of attention toward objects than typically developing toddlers (Swettenham et al. 1998). Similarly, retrospective videotape studies of infants later diagnosed with autism indicate that these infants look less to other people's faces

than typically developing infants (Osterling and Dawson 1994). Cumulatively, these studies suggest that children with ASD scan faces and social scenes differently than controls. The literature reviewed below focuses on recent research that used eye-tracking technology to characterize differences in visual scanning patterns between people with and without autism spectrum disorders.

Current Knowledge

Many studies have reported that children and adults with ASD scan faces, objects, and scenery differently than controls, but the evidence is far from consistent. Some studies find no evidence of atypical visual scanning (e.g., Rutherford and Towns 2008; Van der Geest et al. 2002a). Other studies report atypical visual scan patterns only in certain conditions (e.g., Speer et al. 2007) or in certain age-groups (e.g., Nakano et al. 2010).

Visual Scanning of Faces: Fixation Patterns

Most studies that report atypical scanning patterns in response to faces base this claim on participants' gaze fixation patterns during eye-tracking measures in which images of faces are presented on a video monitor. Individuals with ASD fixate longer (Anderson et al. 2006; Chawarska and Shic 2009; Pelphrey et al. 2002; Trepagnier et al. 2002) and more frequently (Pelphrey et al. 2002) on the periphery of faces and less on internal facial features compared to controls. When participants do look at the internal features of the face, individuals with autism look longer to the mouth (Jones et al. 2008; Klin and Jones 2008; Klin et al. 2002; Neumann et al. 2006) and less to eyes relative to controls (Boraston et al. 2008; Corden et al. 2008; Dalton et al. 2005; Hernandez et al. 2009; Jones et al. 2008; Klin et al. 2002; Klin and Jones 2008; Pelphrey et al. 2002; Speer et al. 2007; Sterling et al. 2008). The observation that adults with ASD look less than controls to the eyes and mouth of still images (Sterling et al. 2008) is compatible with preference for peripheral rather than core features of the face (Anderson et al. 2006; Chawarska and Shic 2009; Pelphrey et al. 2002).

One study found evidence of age-related differences in face-scanning behaviors: children with ASD (age 3–9) looked less to the mouth than controls, but the pattern was reversed in adults (Nakano et al. 2010). Variations of these results have also been reported. For instance, 3- to 6-year-old children with ASD looked longer at the mouth than at the eyes compared to typically developing controls. However, the scanning patterns demonstrated by the ASD group did not differ from that of a younger group of neurotypical controls, 1–3 years of age (von Hofsten et al. 2009). Although 6-month-old siblings of children with autism looked more to the mouth than the eyes (Merin et al. 2007), a follow-up on the same children found no link between eye-mouth preferences at 6 months and autism symptoms or diagnostic classification at 24 months (Young et al. 2009). A study that reported equal fixation time between groups also reported fewer fixations on the eye region by children with ASD than controls (van der Geest et al. 2002b). A study involving adolescents with ASD reported atypical scanning of faces, but differences were in the opposite direction of many of the studies cited above. In response to grayscale images of faces, adolescents with and without ASD fixated longer on the upper region of the face than the lower region, but the ASD group fixated even longer on the upper region than typically developing controls (McPartland et al. 2010).

Multidimensional scaling has been employed to analyze participants' gaze patterns with respect to timing and spatial coordinates simultaneously (Nakano et al. 2010). This analytic method revealed highly consistent scanning patterns among typically developing children and adults and highly variable results among children and adults with ASD. Scan patterns of ASD participants differed considerably from each other, and the ASD group as a whole differed significantly from controls.

Attention Shifting

Eye movements and gaze shifts are measures of interest in studies about face scanning. Two studies report less shifting of visual attention by

individuals with ASD compared to controls during the presentation of dynamic social stimuli (Nakano et al. 2010; von Hofsten et al. 2009). One study investigated visual scanning of dynamic faces using video stimuli in which models were speaking. When the auditory modality was combined with the visual modality, children and adults with ASD shifted their attention away from a speaking model earlier than controls, who continued to watch the model's face until she stopped speaking (Nakano et al. 2010). These results are consistent with the observation that toddlers with ASD diverted their attention away from faces and toward objects more rapidly than controls (Chawarska et al. 2010).

Stimulus Effects

In general, the studies or conditions within studies that did not find evidence of atypical visual scanning of faces by individuals with ASD presented still images of faces (Rutherford and Towns 2008; Speer et al. 2007; Van der Geest et al. 2002b). However, numerous studies that employed still images have reported atypical visual scanning of faces in participants with ASD (Anderson et al. 2006; Boraston et al. 2008; Chawarska and Shic 2009; Corden et al. 2008; Dalton et al. 2005; Falck-Ytter et al. 2010; Hernandez et al. 2009; Neumann et al. 2006; Pelphrey et al. 2002; Sterling et al. 2008). Differences in face-scanning patterns were observed more consistently in studies that presented participants with dynamic social stimuli (Jones et al. 2008; Klin et al. 2002; Klin and Jones 2008; Nakano et al. 2010; Speer et al. 2007; von Hofsten et al. 2009). This pattern of results suggests that visual stimuli that are most similar to real-life visual experience are most effective at capturing atypical scan patterns in people with autism (Klin et al. 2003). Other characteristics of visual stimuli that may contribute to the magnitude of group differences include the color and size of the stimuli and duration of presentation (McPartland et al. 2010). Grayscale and static images may elicit similar visual scanning patterns in typical and ASD participants (Speer et al. 2007).

One study sought to address the effects of stimulus type and presented images of people in

isolation and in social contexts, in both still and dynamic formats (Speer et al. 2007). All images also contained nonsocial scenic elements. The ASD group (males, 9–18 years old) looked less at the eyes and more at the bodies of people presented dynamically in groups, but no group differences were observed in the other three conditions (Speer et al. 2007). Another factor that has been associated with differences in result patterns is the duration of stimulus exposure (McPartland et al. 2010). Studies that presented still images for longer durations did not report less looking to eyes by participants with ASD (Van der Geest et al. 2002b (10 s), McPartland et al. 2010 (8 s)), whereas atypical patterns in participants with ASD were reported in studies that presented images more briefly (e.g., Pelphrey et al. 2002 (2 s)).

Age Effects

The studies and portions of studies in which atypical visual scanning behaviors were not observed involved adolescents (Speer et al. 2007; Van der Geest et al. 2002b) and adults (Rutherford and Towns 2008). One study that compared visual scanning of faces between age-groups reported atypical scan patterns in both children and adults, but the differences between ASD and neurotypical participants changed across development: relative to controls, children with ASD fixated less on the mouth, whereas adults with ASD fixated more on the mouth (Nakano et al. 2010). The concordance of results between the child cohort evaluated by Nakano and the results reported for the same developmental period by von Hofsten et al. (2009) suggests that preferential looking to the mouth may be adaptive early in development. Consistent with this claim, a positive correlation was observed in siblings of children with autism in duration of fixation on the mouth at 6 months of age and language skills at 24 months (Young et al. 2009).

Visual Scanning of Scenes That Contain Social Stimuli

A relatively small body of literature has described the visual scan patterns of individuals with ASD in response to complex scenes that include social

stimuli as well as objects and/or scenery. These studies complement what is known about processing of faces presented in isolation by exploring participants' differential preferences among classes of visual stimuli. The stimuli presented in these studies aim to portray situations that individuals may encounter in their everyday lives (Speer et al. 2007). Relative to controls, adolescents with autism look less to the eyes, more to the body, and more to objects (Klin et al. 2002). This indicates that people with autism do not spontaneously access the same information as controls. Comparable results indicate that adolescents with autism fixate less on faces than on bodies and scenic background (Riby and Hancock 2009). A study that presented human figures among multiple objects did not report differences in looking patterns between children with autism and neurotypical children (Van der Geest et al. 2002a). The Klin study employed dynamic live-action video footage, and the van der Geest study employed static cartoonlike images. The Riby study sequentially presented live-action and cartoon footage in a dynamic format. These distinctions suggest the possibility that, while people with ASD do not differ in looking patterns in all contexts, differences in scanning patterns are more likely to be evident in the context that most closely resembles everyday experience. This interpretation is supported by a fourth study (Nakano et al. 2010) that explored looking patterns in response to live-action video footage of a young girl, who is initially silent, but then announces her name. At the same time that she speaks, a caption appears at the bottom of the screen, providing her name and age in written form. The authors report that children (age 3–9) and adults with ASD looked longer at the text than child and adult controls, respectively (Nakano et al. 2010). The looking patterns of children with ASD were surprising given that most could not read letters. Although text has visual properties that distinguish it from objects and scenery, the finding suggests that children and adults with ASD demonstrate less preferential attention to social stimuli than neurotypical controls. Attenuated preference for social stimuli has also been reported in a study of toddlers with ASD (mean

age = 32 months; Chawarska et al. 2010). Collectively, this pattern of results suggests the possibility that selective attention to nonsocial information during everyday encounters interferes with the achievement of expertise in processing informative social phenomena.

Visual Scanning of Nonsocial Stimuli

Two recent studies have assessed scan patterns of children (Anderson et al. 2006) and adolescents (McPartland et al. 2010) with ASD relative to neurotypical controls in response to static nonsocial visual stimuli. The nonsocial stimuli employed in the Anderson study include animal faces, toys, and landscapes. In addition to evaluating participants' scanning behaviors in response to human faces, the McPartland study presented adolescents with monkey faces, two-dimensional geometric patterns, and three-dimensional curvilinear objects. Reported visual scan patterns differ between the two studies and the associated age-groups. Adolescents with ASD looked to upper portion of geometric shapes and curvilinear objects longer than typically developing controls (McPartland et al. 2010). Among children 1–6 years of age, the only category of stimuli that captured different looking patterns between groups was landscapes (Anderson et al. 2006). In response to still images of landscapes (clouds, rocks, grass, and water), children with ASD demonstrated shorter fixations and less total fixation time than typically developing children and children with cognitive delays. The authors suggest that shorter looking at landscapes may reflect more rapid processing of this class of visual information by children with ASD. This interpretation is consistent with the finding that children with ASD perform better than typically developing children on object-recognition tasks (e.g., Trepagnier et al. 2002). The small sample observed in the Anderson study argues for the need to replicate these findings.

Correlates of Atypical Scanning Patterns

Several of the studies described above have reported associations between visual scanning patterns and other areas of functioning associated with autism. If atypical patterns of visual scanning

are associated with severity of social impairment, this would suggest that a common mechanism underlies strategies for acquiring social information and functioning in the social world. Alternatively, if individuals with autism consistently acquire different information than neurotypical individuals, this may constrain social learning opportunities and alter the development of the social brain. Strong relationships between scanning patterns and autistic symptomatology would suggest that atypical visual scanning is a core feature of autism. Alternatively, scan patterns may be disrupted in a subgroup of people with autism. In support of this latter possibility, a study of 5-year-olds reported that the preference for looking at the mouth relative to the eyes was present in a subset of individuals with autism whose social impairments were more severe than their communication impairments (Falck-Ytter et al. 2010). Other studies have articulated results that apply to the full sample of participants with ASD, less looking to the eyes corresponded with other impairments in people with ASD across developmental stages. These include greater social impairment in 2-year-olds (Jones et al. 2008), low levels of social responsiveness in adolescents (Speer et al. 2007), and higher levels of self-reported social anxiety in adults (Trepagnier et al. 2002). More looking to the mouth at 6 months appeared to be adaptive to the development of communication skills in 24-month-olds (Young et al. 2009), but more looking to the mouth corresponds with worse social outcomes in participants in the wide span from 2 years (Falck-Ytter et al. 2010) to 18 years of age (Speer et al. 2007).

A different pattern of associations was reported when social stimuli were presented in scenes that also contained nonsocial stimuli. In that context, adolescents' longer fixations on the mouth were associated with *greater* social adaptation and *lower* autistic social impairment. In the same study, fixation time on objects was associated with lower social adaptation and greater autistic social impairment (Klin et al. 2002). Differences in patterns of association between scanning behaviors and social functioning confirm that the importance of looking targets varies in relation to

the context. Future research should explore looking patterns to faces in isolation as well as looking patterns to scenes that include faces in order to clarify the implications of preferential attention to one type of stimuli or the other.

Among 4-year-olds with ASD ($n = 9$), decreased looking time to landscapes corresponded with lower levels of restricted and repetitive behaviors (Anderson et al. 2006).

Summary

Support for the claim that visual scanning of social stimuli distinguishes people with ASD from neurotypical controls is plentiful, but not entirely consistent. Some studies find no differences between groups, and others find inconsistent patterns of distinction. Fewer efforts have been made to explore patterns of visual scanning in response to nonsocial stimuli, but there is some evidence of atypical scanning patterns in response to images of objects, patterns, and scenery. The inconsistent findings among studies in this domain of research may be attributable to format of visual stimuli, duration of stimulus presentation, and the age or developmental level of research participants.

Future Directions

Studies of visual scanning behavior show promise for characterizing atypical information-gathering processes in individuals with autism. The summary of findings reported above suggests that additional research is needed to clarify effects of age, stimulus format, and research design with respect to the behaviors of interest. These factors can be evaluated in isolation such that various formats of stimulus can be compared within person as well as between groups. Longitudinal research is needed to determine whether visual scanning patterns change across time. Comparison of stimulus formats across time would also help to clarify relationships with other developmental measures such as communication, social skills, and restricted and repetitive behaviors.

Future research should take steps to standardize means of measuring visual scanning behavior between research sites given the possibility that results differ systematically among eye-tracking devices. The precision needed to characterize and compare scanning behaviors argues for the continued fine-tuning and evaluation of instrumentation used for conducting this kind of research.

Definition

A visual schedule is a type of visual support used to help children anticipate transitions and upcoming activities (Vaughn et al. 2005) and to understand the expected agenda for a given period (e.g., daily schedule, class period schedule). Visual schedules typically consist of pictures, or a combination of pictures and words, that represent the expected activities in the order in which they are to be completed. Visual schedules can be created for an individual child or for an entire classroom.

Visual Supports

Definition

Visual supports can be a type of augmentative communication. Visual supports are graphic cues used to increase an individual's communication skills and understanding of expectations by providing graphic models, prompts, or reminders of

how to participate successfully in interactions and routines. Visual supports can be used to make choices or provide expectations for behavior. Examples of visual supports include picture schedules, video modeling, and Social Stories™.

Historical Background

Some individuals with autism are able to take advantage of visual input more effectively than verbal information. This may be interpreted as individuals with autism having better visual skills than auditory skills. Visual supports may be effective because they are more permanent while verbal information is more transient. The concrete nature of visual supports (e.g., a visual symbol has a specific, unchanging referent) may be the reason that these systems are effective for individuals with autism.

Visual support systems can be used to improve the functioning of individuals with autism. Visual supports allow the individual to organize, understand, and remember information. While using visual supports, individuals are able to participate more readily and effectively in communicative and social interactions. Until the individual has learned the expected behavior, the visual support offers a permanent reference. There is evidence that communication and social interaction skills increase while challenging behaviors decrease as the individual begins to understand the expectations and is provided with a means to communicate appropriately.

Current Knowledge

Visual supports can be a type of augmentative communication. These supports draw upon an individual's strength in understanding visual information since the supports are permanent and easy to understand. Individuals with autism may need the extra details and information that visual supports provide before he/she can respond appropriately.

The types of visual supports and symbols used will be determined by the purpose of the system as well as the individual's needs and abilities.

A symbol, or icon, is a visual representation of a word or concept. These symbols may represent real objects or ideas. When choosing symbols, the symbols should be meaningful to the system user. Examples of symbols include real objects, photographs of objects, simple drawings, printed words, and printed words paired with photographs or drawings. Symbols are more likely to be effective if they are not distracting and irrelevant information is eliminated. After the symbols are chosen, the system user needs to be taught what the symbols represent and how the symbols work as part of the visual support system. In addition, visual supports should be easy for the individual to use and manipulate, sturdy, and flexible (i.e., symbols can change as the situation or individual changes). Supports should be inexpensive and quick to produce as an individual may use numerous systems throughout the day.

There are many examples of visual supports including picture schedules, video modeling, and Social Stories. Picture schedules, photographic activity schedules, and calendar systems visually represent a sequence of events and provide information on when and where something will take place. In addition, the schedule provides information on what will happen next allowing an individual to anticipate future transitions. These systems allow for self-management and prepare the individual for future events. The calendar may include transition cues (i.e., an object or symbol card) which allow the individual to move independently from one activity to another and decrease their reliance on an adult to verbally prompt them. Activity schedules or mini-calendars can be used to show the sequence of steps of an individual activity. Individuals with autism may be better able to complete a routine or activity when the steps are presented in a meaningful way with a clear start and finish. Picture schedules or calendar systems have been used to increase task completion and engagement.

Some visual supports can be used to teach behavioral expectations. Video modeling provides an individual with autism a model of an appropriate behavior via videotape. For example, if the target behavior is social initiations, the person in the videotape would demonstrate an appropriate example of social initiation. Conversely,

video self-modeling provides a model of the actual individual engaging in an appropriate behavior. In this case, the individual with autism would watch a videotape of himself/herself engaging in an appropriate example of social initiation. Video modeling and video self-modeling have been used with individuals with autism to increase conversational skills, initiations, and play behaviors as well as decrease challenging behaviors.

Social Stories are short stories written to describe a situation or behavior that may be problematic for the individual such as initiating and responding during a conversation, responding appropriately, and being flexible to changes to a routine. These stories are usually written in the first person and may or may not contain pictures. The story text describes the situation or behavior in clear terms and includes information on who is involved, what is happening, and where it is happening. The story may include information on social cues and how the individual with autism can respond as well as how other people may feel or react. These stories can be used in a variety of settings (e.g., home, school, day care, community outings, etc.) and may be effective for children with autism, Asperger's syndrome, language impairment, and other developmental disabilities. Social Stories may be effective because they specifically address a deficit in individuals with autism. Social Stories have been used to decrease challenging behaviors (e.g., shouting, tantrums) and increase socially appropriate behaviors (e.g., following directions, maintaining eye contact).

Other examples of visual supports include checklists, visual cues, pictorial prompts, and activity choice boards. These supports may be used to increase task completion, engagement, and choice-making abilities.

Caregivers, educators, and therapists will need to consider many factors to determine which visual support system is most appropriate for an individual. The cost of the system and time to produce the system are two factors to consider. For example, video self-modeling may be a very effective strategy but may be costly for some individuals and take too much time to produce and edit. On the other hand, simple line drawings are inexpensive and quick to produce but may not

meet the needs of some individuals. The physical size of the system also should be taken into consideration. Large calendar systems may be effective for some individuals, but often will need to be shrunk to make them more portable. The smaller system, however, should contain the same information and level of detail as the larger system initially, though it may be possible to fade out details to a more normalized reminder system. Some systems may be more effective for certain behaviors. For example, when engaging in a sequential routine, a dynamic system may be most appropriate as pictures can be added to and removed from the visual support. When an individual completes a step in the routine, he/she removes the associated picture for that step and moves to the next step.

Positive changes in behavior have been documented when using visual support systems where written directions or expectations are supported by pictures or symbols. The pictures or symbols give the individual a static example that he/she can refer to until the expected behavior is learned.

Future Directions

Future research should focus on systems and symbols that produce generalized effects. To improve generalization, multiple exemplars of a symbol within a system may be necessary. During video modeling, multiple examples of social initiation may produce stronger effects than a single example. Multiple examples or symbols to represent the same concept within a Social Story may help individuals generalize their behaviors. For instance, if the story is being used to teach verbal responses, it may be useful to provide multiple examples of verbal responses within the story text. During system development, how the target behaviors may generalize across settings, activities, and people should be considered. A visual support may be very effective at home with a parent but not effective at school with a teacher. Additional training or adaptations to increase generalization should be part of the planning process.

Future research also should focus on maintaining improved behavior outcomes over

time, with and without a system in place. Immediate behavior improvements may be caused by the novelty of a new visual support. Behavior change maintained over time would indicate that the change was a result of the visual support and not simply a novelty effect. Maintaining behavior change after the support has been removed also should be planned. Are individuals able to maintain behavior change over time when using the system? Is the individual able to function as well without the system? If not, are smaller, less intrusive systems able to produce similar results? Adaptations to increase independence should be part of the visual support planning process, especially for older individuals.

Definition

Cognitive potentials are electrophysiological responses to internal or external events that are derived from recordings of brain activity made with an electroencephalogram, or EEG. To record EEG, sensors that detect electrical activity are placed on the participant's scalp and secured with a net, cap, or glue. With millisecond-level resolution, these sensors record the electrical activity that naturally propagates to the scalp from thousands of synchronously firing cortical pyramidal neurons. Cognitive potentials and other measures derived from EEG recordings can thus provide important information about the neurophysiological mechanisms underlying behavioral symptoms of developmental disabilities like autism.

Cognitive potentials are derived by time-locked averaging of segments of EEG recorded during a series of similar events (such as pressing

a button or viewing a particular type of stimulus). This averaging technique enables brain activity related to the event to be at least partially dissociated from other processes because randomly distributed "background" brain activity is minimized, while activity that occurs with a reliable temporal relation to the stimulus is retained. The resulting "event-related potential" (ERP) waveform has a characteristic pattern of peaks and troughs that have been termed "components," and the amplitude and latency of particular components are typically sensitive to particular types of event.

Components are typically labeled by polarity (P for a positive-going deflection, N for a negative-going deflection) and absolute or relative timing (e.g., the P300 is a positive-going deflection that peaks approximately 300 ms after an event occurred or the P3 is the third positive-going deflection after an event occurred). Component characteristics like latency and amplitude can be measured to examine the speed and efficiency of particular cognitive processes, although it is also recognized that visible components likely represent the summation on the scalp of several different underlying sources of neural activity. Early components that are related to sensory processing are commonly termed "evoked potentials" and typically occur within 300 ms of an event; later components occurring between 300 and 2,000 ms of the event are often referred to as "cognitive potentials" and are the focus of this section. Cognitive potentials likely reflect neural activity associated with "higher-level" cognitive processes like memory, attention, error detection, inhibition, and semantic processing and can thus provide insight into the neural correlates of cognitive functions that appear atypical in autism.

Historical Background

The use of EEG to measure brain activity in humans dates back to Hans Berger's recordings of the brain activity of his young son in the 1920s, although Richard Caton had earlier recorded responses to sensory stimuli in animals in

nineteenth-century Liverpool (for a history of the early use of EEG, see Brazier 1961). The event-related potential (ERP) technique was developed in the late 1940s and at that time involved the photographic superposition of several time-locked EEG traces. Although later analog-averaging techniques increased efficiency, it was the introduction of digital signal processing methods that made ERP feasible for larger research studies. In the twentieth century, the information technology revolution transformed the recording, acquisition, and analysis of EEG and enabled the introduction of high-density electrode arrays, faster sampling rates, and more sophisticated analytic techniques.

The potential of EEG for revealing information about the nature of neural impairments in autism was recognized from the early development of the techniques, with the first published reports of event-related potentials in autism emerging in the 1960s. Most early studies focused on the P300, a clearly visible positive-going deflection that is elicited by a wide range of events and is modulated by factors such as attention, probability, novelty, and task relevance. With the development of increasingly powerful acquisition and analysis systems, work expanded to examine other components over multiple electrodes. Although the majority of EEG studies have been conducted with older and higher-functioning participants, the advent of high-impedance EEG recording arrays that afford more rapid application and do not require scalp abrasion has facilitated more recent work with individuals with autism who are younger and have fewer adaptive skills. Such developments in EEG technology have led to an expanding body of knowledge about the neural correlates of a range of cognitive abilities in autism, described in the next sections.

Current Knowledge

Face Recognition

Many individuals with autism report difficulties with recognizing familiar faces, and interpreting the signals provided by familiar faces is central to successful social interaction. Understanding the

source and development of difficulties with face processing facilitates the design of effective interventions and may also provide deeper insight into the process of symptom development in autism. Recent models of the development of face processing emphasize the interaction between “expected” experience with faces in the child’s environment and congenital commitment of neural regions with the computational and anatomical qualities optimal for processing complex stimuli like faces. Are face recognition difficulties in autism related to congenital dysfunction in these neural regions, or could they be related to disruptions to the specialization process caused by a lifetime of reduced self-directed experience with faces? Testing the early development of face-processing skills in children with autism is central to testing such proposals.

In a series of studies, Dawson, Webb, Jones, and colleagues have used event-related potentials to examine the development of neural responses to familiar and unfamiliar faces in individuals with autism from toddlerhood to adulthood. Event-related potentials can provide particularly valuable developmental information because the same methodology and paradigms can be used across a wide age range. In this set of studies, participants watched repeated pictures of an unfamiliar face and a highly familiar face (a parent or loved one) while EEG was recorded with a high-density sensor array. Key cognitive potentials examined in the younger populations included the Nc, a negative-going deflection observed over frontocentral regions and associated with attention; in adulthood, analyses focused on the posterotemporal N250 and N400, negative-going deflections associated with identity processing.

In an initial study, Dawson et al. (2002) found that typically developing 3- to 4-year-old children showed a significantly more negative Nc response to an unfamiliar face than a familiar face, indicating that they recognized the familiar face. In contrast, in 3–4-year-old children with autism, ERP responses to familiar and unfamiliar faces did not significantly differ over any examined component. Critically, responses to familiar and unfamiliar objects in the group with autism were relatively typical, suggesting that disruptions to

familiarity processing may be face-specific. Since the familiar face was a picture of the child's mother, could this mean that children with autism did not recognize a picture of their primary caregiver? Possibly, but subsequent studies support an alternate explanation. In typical development, Nc responses to faces change over early childhood such that initially larger (more negative) responses to a highly familiar face during infancy become larger responses to the face of a stranger by age 3–4 years, with a transitional period around the end of the second year of life during which responses to highly familiar and unfamiliar faces are not significantly different. Possibly, the 3–4-year-old children with autism tested by Dawson et al. (2002) were showing the pattern associated with younger typically developing children: the transitional stage between larger neural responses to a familiar versus unfamiliar stimulus. If so, this might suggest that children with autism may have a developmental delay in the effect of facial familiarity on the neural correlates of attention.

To test this possibility, Webb et al. (2011) examined event-related responses to familiar and unfamiliar faces in 18–30-month-old toddlers with autism and two groups of typically developing toddlers. The first group of typically developing toddlers were chronologically age-matched to the toddlers with autism and as expected did not show differential responses to the familiar and unfamiliar faces. The second group of typically developing toddlers was aged between 12 and 18 months and had socialization skills that matched the group of older toddlers with autism. Replicating previous work, this group of toddlers showed greater Nc responses to the familiar than the unfamiliar face. Critically, we predicted that the 18- to 30-month-old toddlers with autism would show Nc responses to the familiar and unfamiliar face that matched those of the 12- to 18-month-old typically developing toddlers. This prediction was confirmed: 18- to 30-month-old toddlers with autism showed significantly greater Nc responses to the highly familiar face than the unfamiliar face. Further, stronger socialization skills as measured by parent report were correlated with a more mature pattern of neural response to familiarity in both groups. These

findings confirm that toddlers with autism can recognize their parent from a static picture, but suggest that the modulation of attention to faces by familiarity was delayed in line with the development of socialization skills in this group. This is consistent with the possibility that developmental delays in face recognition in children with autism may in part be related to children's reduced self-directed social experiences with faces in their natural environment.

Consistent with the possibility that disruptions in the early neural correlates of familiar-face recognition are development delays rather than absolute impairments, Webb et al. (2010) found that N250 and N400 responses to highly familiar and unfamiliar faces did not significantly differ between a group of adults with high-functioning autism and a group of age- and IQ-matched neurotypical controls. Although it remains possible that low-functioning adults with autism would show continued impairment, these results suggest that early neural correlates of face familiarity processing have become relatively neurotypical for at least some adults with autism. Interestingly, this group of adults did show behavioral impairments in a face recognition battery that required them to identify a set of previously presented faces from related distracters. Investigating the neural correlates of encoding and recognition of initially unfamiliar faces may reveal impairments that are not apparent when examining responses to a highly familiar face with affective significance. In addition, deficits in “executive” processes like selective attention, decision-making, resistance to interference, or forming face-context associations may also make a stronger contribution to behavioral or “real-life” difficulties with face recognition in adulthood than deficits in the systems involved in generating the earliest signals that a face is familiar. Addressing these questions may provide important insight into the deficits that underlie difficulties with face recognition in individuals with autism and may suggest fruitful avenues for intervention.

Emotion Processing

Expressing and interpreting emotions can be challenging for many individuals with autism, but the

neurophysiological disruptions that underlie this difficulty remain unclear. Recording EEG responses to pictures of faces depicting different emotional expressions provides one way to examine the integrity of very early facial emotion-processing systems in autism. In an initial study, Dawson and colleagues studied neural responses to neutral and fearful faces in 3–4-year-old children with autism or typical development (Dawson et al. 2004). While neural responses to fearful and neutral faces differed within 300 ms of stimulus presentation for typically developing children, the group of children with autism showed no significant differences in neural response to the two types of stimulus over any examined component. Interestingly, faster responses to emotional faces at the posterior N300 were correlated with increased social attention in children with autism, suggesting that more efficient processing of facial emotions was related to stronger social skills in this group. Consistent with developmental delay in this area, cognitive potential responses to emotional expressions in older children with autism appear more neurotypical, although the neural sources underlying scalp-recorded activity may be weaker and/or slower than those observed in typically developing children (Wong et al. 2008). Possibly, individuals with autism “catch up” with their neurotypical peers in simple emotion-processing tasks, although impairments may remain in more complex aspects of emotion processing (e.g., integration with gaze, parallel processing with the semantic content of an interaction, or rapid transitions between different emotions). Examining the longitudinal developmental trajectory of neural responses to emotional expressions in children with autism would provide insight into this possibility.

Attention

Although not part of the diagnostic triad, difficulties with attention are common in children on the spectrum and often present significant challenges to caregivers and therapists. One event-related component that is clearly modulated by attention is P300, a well-characterized component that likely reflects neural generators in the temporal,

parietal, and frontal areas. P300 is often examined during “oddball” tasks, in which frequent, infrequent, and “novel” (or distinctive) stimuli are presented in visual, auditory, or somatosensory modalities. Typically, P300 responses are larger to infrequent and novel stimuli because attention is engaged by their unusual or unpredicted nature. Recent work suggests P300 comprises two separable components: the early frontocentral P3a, peaking between 250 and 280 ms after stimulus presentation and related to the engagement of attention and novelty processing, and the later parietal P3b, peaking around 300 ms and more sensitive to stimulus probability. Examining P3a and P3b can thus provide insight into the neurophysiological and cognitive mechanisms that underlie problems with attention in autism. Further, since atypicalities in attention are some of the more commonly medicated associated symptoms of autism, examining responses in P300 paradigms could identify potentially sensitive indices of treatment response.

In one of the earliest studies to find atypical P300 responses to visual stimuli in autism, Ciesielski, Courchesne and Elmasian (1990) tested 14 high-functioning adults with autism and 14 age-matched controls. Participants saw a series of green or red flashes, mixed in with a series of 1- or 2-kHz sounds. Each block contained frequent and rare flashes and sounds, and participants were asked to press a button in response to either the rare sounds (the focused auditory attention condition) or the rare flashes (the focused visual attention condition). Results showed that the group with autism showed significantly diminished P3 responses to the targets in both auditory and visual modalities, and this was also observed in a subgroup of adults with autism whose behavioral performance matched that of the neurotypical control group. Since diminished P300 responses are thought to reflect reduced attention, these results may suggest that the capacity for rapid goal-directed modulation of attention may be atypical in autism. However, there must be significant compensatory mechanisms that enable successful task performance despite atypical early neural responses to the stimuli. Identifying these compensatory mechanisms and their

developmental trajectories may be important in identifying effective intervention strategies for attention problems in autism.

Notably, not all studies have observed atypical visual P300 responses in autism, and when disruptions are observed, they are generally milder than for other sensory modalities. For example, Courchesne, Lincoln, Kilman and Galambos (1985) conducted a visual and auditory target detection task with high-functioning adults and adolescents with autism and chronological age-matched controls. Atypicalities in the P300 response to targets were more clearly apparent for auditory than visual stimuli. In a further example, Kemner, Verbaten, Cuperus, Cafferman and Engeland (1994) used oddball tasks with abstract figures and electromagnetic pulses with age-matched groups of 7- to 13-year-old children with autism, typical development, ADHD, or dyslexia. The group with autism showed *larger* P300 responses to novel visual stimuli, but *diminished* somatosensory P300 responses relative to neurotypical controls (though not relative to the other control groups). Taken together, findings suggest that attention may operate with differential efficiency across sensory modalities in autism. However, it is also possible that variability in adaptive or cognitive skill between participant groups is a critical factor. For example, Salmond, Vargha-Khardem, Gadian, de Haan and Baldewag (2007) studied auditory P300 responses in an oddball task with low- and high-functioning 8- to 20-year-old individuals with autism. While the low-functioning group showed a slower P3a and a diminished P3b response to targets, the high-functioning group did not differ from controls in the latency or amplitude of any component. Further, in a group of 5- to 11-year-old children with autism, Gomot et al. (2010) found that an atypically large P3a to deviant sounds was related to decreased tolerance of change, as reported by trained nurses who cared for the children in a hospital psychiatric day-care unit. These studies provide supporting evidence that attention is related to symptom variability in autism and suggest that interventions targeting domains of attention may have broad effects for individuals with autism.

In addition to measuring the ability to “tune in” to relevant stimuli, P300 can be used to examine the ability to “tune out” stimuli that are not relevant to an ongoing task. In paradigms where participants are asked to respond to targets and ignore nontargets, P300 responses to nontargets are typically diminished. However, Sokhadze et al. (2009) found that relative to neurotypical controls, P3b responses to nontargets were larger and responses to targets were smaller in a group of adolescents and adults with autism. This “flatter” response profile suggests that the group with autism were less able to focus their attention on a selected stimulus type. The authors suggest that early inefficient perceptual filtering may lead to a greater need to actively inhibit nontarget stimuli at a later processing stage. Interestingly, in this study, P300 was examined as part of a suite of outcome measures for testing the efficacy of low-frequency repetitive transcranial magnetic stimulation (rTMS) of dorsolateral prefrontal cortex for symptoms of autism. In individuals with autism who received rTMS, the amplitude of P3a response to nontargets significantly decreased between pre- and post-TMS assessment points, while no changes were observed in the wait-list control group. The authors suggest that TMS treatment may have improved selective attention by strengthening the inhibitory surround of minicolumns in dorsolateral prefrontal cortex. This study illustrates the possible benefits of including event-related potential measures in treatment research, both because of their potential sensitivity to subtle treatment effects and because they may provide greater insight into neurophysiological mechanisms underlying treatment response.

P300 responses can also be used to study spatial attention shifting in autism. Many individuals with autism have difficulty shifting their attention between one object and another or shifting gaze between a person and the object to which they are referring. To understand more about attention shifting in autism, Townsend et al. (2001) examined P300 in nine high-functioning adults with autism and chronological age-matched controls. Adults were presented with an array of five squares and instructed to look at a fixation cross that remained in the center of the screen. On each

trial, one of the squares would change color to indicate the upcoming location of the target stimulus on that trial. Participants were asked to respond to target stimuli, but not to respond to stimuli that appeared in noncued locations. Because participants had to pay attention to the cued box while looking at the central stimulus, this is a test of covert attention shifting. EEG results showed that the frontal P3a response to peripheral stimuli was delayed or absent in individuals with autism, and behavioral results also showed lower detection accuracy for peripheral versus central stimuli in the autism group only. Since P3a is typically associated with attention engagement, the atypical P3a response may indicate that the covert spatial orienting system operates less efficiently in autism. Further, a range of evidence suggests that the integrity of the cerebellum can modulate the cortical activity that contributes to the frontal P3a. Townsend and colleagues thus suggest that impairments in attention shifting in individuals with autism may be related to the influence of cerebellar pathology on frontal and parietal spatial systems. In addition to providing important insight into attention impairments in autism, this study illustrates how cognitive potentials allow researchers to begin to investigate the neuropathological and neurophysiological correlates of behavioral challenges in autism.

Goal-Directed Learning

Individuals with autism often have difficulty with cognitive skills required for flexible, goal-directed behavior like inhibition, planning, and regulatory control. These “executive functions” also appear to be related to variability in adaptive functioning and sociocommunicative development in individuals with autism (e.g., Munson et al. 2008) and are thus important potential predictors of developmental outcome. One executive skill critical to goal-directed learning is the ability to modify behavior based on internally or externally generated error signals, and cognitive potentials can provide insight into the integrity of those signals in autism. For example, making an error is associated with the frontal error-related negativity (ERN), which occurs within 500 ms of the

participant’s response and is thought to reflect internal error monitoring. Examining the integrity of ERN thus provides insight into the integrity of internally generated error signals in autism.

In an initial study, Henderson et al. (2006) found that high-functioning 11-year-old children with autism showed a larger ERN than IQ-matched controls or lower-functioning children with autism. Since a larger ERN would be typically associated with more effective error monitoring, these findings might suggest that children with autism require particularly strong executive functioning skills to develop language. However, several subsequent studies have obtained different results. For example, Vlamings, Jonkman, Hoeksma, van Engeland and Kemner (2008) found that 10-year-old children with autism had a smaller ERN than typically developing controls and that this was not associated with IQ. Source analysis suggested that the reduced ERN reflected diminished brain activity in the anterior cingulate, suggesting that disruptions in error processing may be related to pathology in this brain region. Similarly, South, Larson, Krauskopf and Clawson (2010) also observed a reduced ERN in a group of 8- to 18-year-olds with autism; correlations were observed with parent reports of social behaviors, suggesting relations between error processing and social symptoms in autism. Tying together these findings, Santesso et al. (2010) found a reduced ERN in high-functioning adults with autism, linked this to reduced activity in the anterior cingulate, and observed relations between increased anterior cingulate activity and better social skills. Taken together, the weight of evidence suggests that individuals with autism may have diminished activity in the anterior cingulate gyrus and a corresponding difficulty with response monitoring and error awareness that may be related to their degree of social impairment.

If individuals with autism have difficulty generating internal error signals, might external feedback be particularly important to learning? The presentation of external feedback is associated with a negative-going deflection called feedback-related negativity (FRN) that is typically more negative to losses or unexpected

outcomes than gains or expected outcomes. A recent study of children and adolescents with autism observed relatively neurotypical FRNs to concrete rewards (Larson et al. 2010), despite the diminished ERN that was observed in a substantially overlapping group of children (reported in South et al. 2010). Larson et al. (2010) suggest that the response to internally generated error signals may be more impaired than response to concrete, direct feedback in autism. Although more work is required to consolidate these findings, if children with autism are more able to benefit from external feedback than internally generated error signals, there may be important implications for the design of intervention programs.

Movement-Related Potentials

The presence of stereotyped and repetitive motor mannerisms is currently one of the diagnostic criteria for autism. Although there are many hypotheses as to the sources of such behaviors, diminished volitional control of movement could contribute to restricted movement patterns. The movement-related potential (MRP) or Bereitschaftspotential is a negative-going deflection observed when movements are internally generated. The MRP typically peaks when the movement is made and is maximal over central electrodes. Studying the MRP may provide insight into volitional control of movement in autism.

Two related studies have examined the MRP in groups of adults with autism or neurotypical development. Rinehart et al. (2006) used a paradigm in which participants had to press illuminated buttons until the light turned off, such that the duration of each button press was full cued. In this task, the group of adults with high-functioning autism showed a slower MRP offset than the other groups, suggesting that activity associated with movement preparation took longer to dissipate after the movement was generated. In a follow-up study, Enticott, Bradshaw, Iansek, Tonge and Rinehart (2009) modified the paradigm to decrease the provision of external cues for movement generation; participants were asked to press a button at set intervals, with no

external cues to which button to press or when. In this version of the task, the MRP peaked significantly earlier in adults with high-functioning autism than those with Asperger's syndrome and neurotypical adults, again consistent with disruptions in movement preparation. Difficulties with movement preparation may contribute to difficulty with sport or other activities that require fine-grained movement control and could possibly contribute to decreased movement generativity in autism. Studying relations between the MRP and restrictive and repetitive behaviors would be an important next step in this area.

Future Directions

Developments in technology continually afford new research questions in the field of cognitive potentials. The advent of high-density electrode arrays and more powerful source analysis techniques will enable researchers to ask more detailed questions about the neural sources underlying scalp-recorded potentials. However, it is important that the field strives to be representative of the full autism spectrum. The development of low-profile rapid application electrode arrays facilitates the use of EEG with infants, young children, and individuals with autism with more limited adaptive skills. Nonetheless, appropriate use of EEG with these populations requires extensive practice, experience, and training, and developing and disseminating gold-standard procedures for collecting and analyzing data from these relatively understudied groups is an important future goal.

Examining the relation between cognitive potentials and genetic variation is also an important goal for the field. Understanding how particular neurophysiological or cognitive processes relate to genetic risk markers in children with autism or their family members will help us evaluate whether cognitive potentials could provide valuable endophenotypes of autism. There is promising evidence that family members of individuals with autism may show disrupted event-related responses to social stimuli that resemble

those observed in some individuals with autism (Dawson et al. 2005), and examining these responses in relation to particular genetic markers is an important next step.

A further important direction is the integration of cognitive potentials into treatment studies. Many treatment studies currently use global indicators that are not specific to the neural systems that are the hypothesized target of the drug. Furthermore, many more global outcome measures may not be sensitive to subtle changes that occur soon after the drug regime begins and, if reliant on parent report, may suffer from inflated placebo effects. Measuring cognitive potentials may provide a more sensitive, specific, and objective complementary means of assessing response to treatment. Treatment-related ERP changes have been observed with pharmaceutical compounds (Verbaten et al. 1996) and transcranial magnetic stimulation (Sokhadze et al. 2009), indicating that this is a promising approach. One current limitation to the use of EEG in treatment studies is the lack of a standardized “battery” of tasks designed to load on particular cognitive systems; developing such a battery would be an important step forward.

Finally, understanding the developmental emergence of symptoms of autism is a critical step toward identifying critical periods and potential targets for intervention. EEG is a technique that can be used across the lifespan and is therefore ideally suited to longitudinal or cross-sectional investigations of neurophysiological development in autism. However, there are currently very few studies of under-fives with autism. The current wave of infant sibling studies will provide more information about very early development in children at risk for developing autism, and several labs are examining event-related potentials in this population. These studies will provide valuable information about the early emergence of neurophysiological patterns observed in older children and adults and enable questions about their developmental origins. Understanding the neurodevelopmental trajectories that result in an autism diagnosis is critical to developing effective systems for early detection and early intervention, key steps toward

improving the lives of individuals with autism and their families.

Definition

Visual-motor function is the integration between visual perception and motor skills. More specifically, visual-motor function is the ability to draw or copy forms or to perform constructive tasks integrating both visual perception and motor skills. Visual-motor function involves the ability to coordinate vision with the movements of the body. Due to the body, head, eyes, and limbs being constantly in motion, every time an individual wants to carry out an action, calculations and decisions about orientation, motion, and location need to be made. The parietal cortex is the part of the brain that is responsible for processing and integrating somatosensory, visual, and auditory information and plays an important role in producing planned movements. The cerebellum, brainstem, and frontal lobe are also involved in visual-motor abilities. Visual-motor function deficits can lead to learning disabilities, neuropsychological deficits, and behavioral problems. For example, deficits in visual-motor function may lead to problems with fine motor tasks that rely heavily on visual feedback such as writing, drawing, painting, building structures with blocks, stringing beads, repairing things, and playing games. Visual agnosia and apraxia are other disorders associated with visual-motor function deficits. The presence of visual, sensory, or motor deficits is not specific to but is very common in autism. The Bender Visual-Motor Gestalt Test, Second Edition (BG-II), Beery-Buktenica Developmental Test of Visual-Motor Integration (Beery VMI), and the Wide Range Assessment of Visual-Motor Abilities (WRAVMA) are common psychological assessments that assess visual-motor function.

Description

The *Beery-Buktenica Developmental Test of Visual-Motor Integration* (Beery VMI) is a visual-motor screening tool used to identify children, adolescents, adults, and seniors, aged 2–100 years, who are experiencing difficulty coordinating visual perception and motor (finger and hand) movements (Beery and Beery 2010). The Beery VMI consists of 30 geometric designs of increasing complexity that participants are asked to copy. The specific Beery VMI items are listed in Table 1. It can be administered to individuals or groups and takes about 10 min to complete. The 30-item Full Form can be used with all age groups, 2–100 years, while the 21-item Short Form can be used with children ages 2 through 7 years.

Two additional standardized tests, the *Beery VMI Visual Perception Test* (VPT) and the *Beery VMI Motor Coordination Test* (MCT) are

^aBeery and Beery (2010)

^bBeery VMI items 1, 2, and 3 do not need to be administered if a child is able to copy one or more of items 4, 5, or 6. The Beery VMI Short Form consists of items 1–21 and is designed for use with children aged 2–7 years. The Beery VMI Full Form contains all 30 items and can be used with participants aged 2–100 years

also available for child and adult participants to complete, and this facilitates the comparison of an individual's separate visual and motor performance skills. The VPT requires examinees to identify a target design among choices, and the MCT requires examinees to trace geometric shapes with a dashed outline using a pencil without an eraser. Each supplemental test takes about 5 min to complete. "The two tests use the same stimulus forms as the Beery VMI, unlike other visual-motor test batteries that mistakenly compare less related stimuli and tasks" (Beery and Beery 2010, p. 2). Although administration of the VPT and MCT are not necessary, it is suggested that if they are used, the Beery VMI should be administered first, followed by the VPT and then the MCT.

The Beery VMI is used by psychologists, educators, and allied health professionals to assess children and adults with presenting known or suspected developmental, behavioral, learning, neurological, or psychological difficulties including individuals with autism spectrum disorder (ASD) (Fulkerson and Freeman 1980; Lopata et al. 2007; Novales 2006; Volker et al. 2010). Individuals administering the test must have Examiner B qualifications, which includes a graduate degree in a related field (such as psychology, occupational therapy, education, speech therapy, physiotherapy, or health sciences) or equivalent training to complete the assessment. The Beery VMI is a paper and pencil test that must be hand-scored by the examiner.

The scoring sheet is included as part of the Beery VMI test booklet. Copied shapes and designs receive either a score of "1" for being correct or "0" (no-score) for items not copied correctly (Beery and Beery 2010). Specific guidelines regarding scoring are provided in the manual including pictorial examples as well as specific written scoring criteria for each geometric form. Accurate scoring requires the use of a protractor to make judgments about accuracy of angles, etc. The administration of the Beery VMI, VPT, and MCT items and scoring is stopped after three consecutive forms have received a "no-score." The raw score consists of the total number of correct forms until the ceiling score is reached

(e.g., three consecutive wrong items). The raw score is converted to the standard score using the conversion tables provided and then the standard score is used to calculate the percentile rank for the child's specific age range. Tables for each of these scores are provided in the test manual. The test manual also contains tables to convert raw scores into age equivalents.

Four supplemental materials are available in addition to the Beery VMI that can be used to enhance the teaching of visual-motor integration skills to children include the following:

- The *Beery VMI Stepping Stones Parent Checklist* that includes about 200 of the "Stepping Stones" milestones that a parent can observe and note on a check list (Beery and Beery 2010).
- The *Beery VMI Developmental Teaching Activities* that contains about 250 activities geared to assist children from birth to age 6 develop skills to promote skill development (Beery and Beery 2010).
- The *Beery VMI My Book of Shapes* that provides 100 activities that may help with the learning of letter and numeral shapes (Beery and Beery 2010).
- The *Beery VMI My Book of Letters and Numbers* that extends upon the *My Book of Shapes* activities and provides 100 additional exercises designed to provide more practice with numerals and upper- and lower-case letters (Beery and Beery 2010).

Historical Background

The Beery VMI, consisting of 24 items, was first published by Beery in 1967 and has retained its original forms, characteristics, and strengths. Geometric forms, rather than letters or numbers, were selected as the basis for the test's items, to minimize the impact of culture and/or education. "The Beery VMI was standardized six times between 1964 and 2010 with a total of more than 13,000 children. It was also nationally standardized in 2006 with 1,021 adults" (Beery and Beery 2010, p. 1). In the 1997 version, two supplemental

standardized tests – the *Beery VMI Visual Perception Test* (VPT) and *Beery VMI Motor Coordination Test* (MCT) – were added which allowed users to statistically compare an individual’s visual and motor contributions to visual-motor integration. The Beery VMI was revised in 2004 consisting of 30 geometric forms and included an extended age range for its norms down to 2 years of age (Beery and Berry 2004). As well, the authors identified 600 “Stepping Stones” or milestones that may serve as precursors for visual-motor integration for children from birth through to age 6. The Stepping Stones have been listed in both the Parent Checklist and in the Beery VMI test manual as a reference guide. Developmental Teaching Activities based on the Stepping Stones were also developed for this edition. During the 2006 revision of the Beery VMI, adult norms were added to include participants aged 19–99 years, 11 months. “The Beery VMI and its supplemental *Visual Perception* and *Motor Coordination* tests were renormed in late 2009 and 2010 on children obtained from the four major census regions in the United States” (Beery and Beery 2010, p. 100).

Psychometric Data

A wealth of psychometric data has been reported for the Beery VMI during its six revisions. The information reported here focuses on the most recent reliability and validity data reported in the sixth edition of the Beery VMI manual published in 2010. Types of reliability data often reported includes internal consistency, test-retest/time sampling reliability, inter-rater/inter-scorer reliability, and intra-rater reliability. For participants aged 2–17, the Cronbach alpha coefficients for the Beery VMI ranged from 0.79 to 0.89 with a mean of 0.82, for the VPT ranged from 0.74 to 0.87 with a mean of 0.81, and for the MCT ranged from 0.71 to 0.89 with a mean of 0.82. For the adult group aged 19–100 years, the Cronbach alpha coefficients for the Beery VMI ranged from 0.85 to 0.94 with a mean of 0.89, for the VPT ranged from 0.83 to 0.93 with a mean of 0.88, and for the MCT ranged from 0.84 to 0.89 with a mean of 0.86 (Beery and Beery 2010). The

Standard Errors of Measurement (SEMs) for the Beery VMI, VPT, and MCT designed for children ages 2–17 were 5.5, 6, and 6, respectively (Beery and Beery 2010). The SEMs for the Beery VMI, VPT, and MCT for adults ages 18–100 years were 5, 5, and 6, respectively (Beery and Beery 2010).

Related to test-retest reliability, the Beery VMI sixth edition, VPT, and MCT were administered to 142 children between the ages of 5 and 12 years presenting with a range of abilities. “The time between initial administration and the retest averaged 14 days. The overall test-retest coefficients were .88 for the Beery VMI, .84 for Visual Perception, and .85 for Motor Coordination” (Beery and Beery 2010, p. 107). In the Beery VMI manual, 1-week test-retest reliability coefficients for a sample of 20 adult participants aged 60–69 years were reported as 0.88, 0.86, and 0.84 for the Beery VMI, VPT, and MCT, respectively (Beery and Beery 2010).

For inter-rater reliability, the Beery VMI Manual reported the results of two individuals who independently scored 100 Beery VMI, VPT, and MCT forms randomly selected from the sample of the children’s norming group. “The resulting interscorer reliabilities were .93 for the Beery VMI, .98 for Visual Perception, and .94 for Motor Coordination” (Beery and Beery 2010, p. 108). Similarly, based on a randomly selected sample of 25 adults from the norming sample, inter-rater reliability coefficients of 0.94, 0.97, and 0.92 were obtained from the Beery VMI, VPT, and MCTs, respectively (Beery and Beery 2010). No information on intra-rater reliability was reported in the Beery VMI manual for child or adult versions of the Beery VMI, VPT, and MCT.

Types of validity often reported for tests include content validity, criterion-related reliability, and construct validity. Two subtypes of criterion-related reliability frequently included are concurrent validity and predictive validity while subtypes of construct validity often reported include factor analysis validity, discriminant validity, convergent validity, divergent validity, and rating scale validity. Content validity was established for the Beery VMI, VPT, and MCT through an extensive literature review and based on clinical experience of the author. Concurrent

validity evidence was established by correlating the Beery VMI with the *Copying* subtest of the *Developmental Test of Visual Perception – 2nd edition* (DTVP-2) and the *Drawing* subtest of the *Wide Range Assessment of Visual-Motor Abilities* (WRAVMA). The correlation between the Beery VMI and the DTVP-2 Copying subtest was 0.75 and 0.52 with the WRAVMA *Drawing* subtest. A correlation of 0.62 was obtained between the VPT and the DTVP-2 *Position-in-Space* subtest while a correlation of 0.65 was obtained between the MCT and the DTVP-2 *Eye-Coordination* subtest (Beery and Beery 2010). “These results generally support the validity of the Beery VMI and its supplemental tests, although correlations are only moderately high between the Beery VMI and the newer, less well-developed geometric form-copying tests [the DVTP-2 and the WRAMA]” (Beery and Beery 2010, p. 111).

Predictive validity evidence of the Beery VMI has also been reported with visual-motor integration (VMI) skills being found to be effective predictors of reading difficulties, letter identification, reading readiness, school-related problems, school achievement, and school grade failures and retentions in children (Goldstein and Britt 1994; Pianta and McCoy 1997). “Generally, researchers have found the Beery VMI to be a valuable predictor, particularly when used in combination with other measures” (Beery and Beery 2010, p. 121).

Extensive construct validity information is reported in the Beery VMI manual in the form of seven hypotheses. Firstly, the skills measured by the Beery VMI, VPT, and MCT are related to chronological age. The Pearson correlation coefficients between the Beery VMI, VPT, and MCT and the ages of the children’s total norming sample were 0.89, 0.85, and 0.84, respectively. Secondly, it was hypothesized that the abilities measured by the Beery VMI, VPT, and MCT would at least be moderately correlated with one another. The correlation between the Beery VMI and VPT was 0.36, between the Beery VMI and the MCT was 0.30, and between the VPT and the MCT was 0.46 (Beery and Beery 2010). Thirdly, the authors provided evidence that the VPT and

MCT each measure a part, but not the entirety, of what the Beery VMI measures. In other words, the “Beery VMI whole is greater than the sum of its parts [the VPT and MCT]” (Beery and Beery 2010, p. 115).

Fourthly, it was proposed that the Beery VMI, VPT, and MCT would be related to the nonverbal aspects of intelligence. The manual reports correlations between the *Revised Wechsler Intelligence Scale for Children* (WISC-R) and the Beery VMI, VPT, and MCT for a sample of 17 children between the ages of 6 and 12 years. The correlations between the WISC-R Verbal IQ and the Beery VMI, VPT, and MCT were 0.48, 0.43, and 0.41; between the WISC-R Performance IQ and the Beery tests were 0.66, 0.58, and 0.55; and between the WISC-R Full IQ and the Beery tests were 0.62, 0.54, and 0.51, respectively (Beery and Beery 2010). The fifth proposition was that the Beery VMI, VPT, and MCT would be related to academic achievement. In the manual correlations between the *Comprehensive Test of Basic Skills* and the three Beery tests were reported as 0.63, 0.29, and 0.40 (Beery and Beery 2010). The sixth hypothesis stated that the Beery VMI, VPT, and MCT measure similar traits and are effective in measuring persons. Using the Rasch Measurement Model, evidence of high item and person separation indices were reported thus confirming this hypothesis.

The seventh hypothesis proposed that the Beery VMI, VPT, and MCT would be sensitive to certain disabling conditions with groups of participants with known diagnoses would obtain lower test scores. A multitude of studies have been published documenting that the Beery tests are able to differentiate groups with a variety of clinical conditions including learning disabilities, dyspraxia, dysgraphia, mental retardation, visual impairment, ASD, spina bifida, fetal alcohol syndrome, leukemia, Tourette syndrome, cerebrovascular accident, traumatic brain injury, Parkinson’s disease, amyotrophic lateral sclerosis, multiple sclerosis, dementia, and Guillain-Barre Syndrome to name a few.

The Beery VMI has five main weaknesses in relation to its psychometric properties. Firstly, no intra-rater reliability data is reported in the test

manual. Secondly, with the extension of the Beery VMI to include 2-year olds as well as adults aged 19–100 years, it is not clear whether the current version adequately measures VMI in these two participant age groups since much of the reliability and validity data reported in the test manual are based on studies that used earlier editions of the Beery VMI (Graham 2007). Thirdly, limited construct validity information about the VPT and the MCT are reported in the test manual. Fourthly, the Beery VMI manual cites a number of studies as evidence of its predictive validity; however, few of them are less than 5-years old. The rest of the cited studies are quite dated being 10–25+ years old (McKnight and Chandler 2007). Finally, the Beery VMI manual does not report any validity information related to the consequences of its use, either positive or negative (American Educational Research Association, American Psychological Association and National Council on Measurement in Education 1999).

In a recent study, Lim et al. (2015) examined the cross-cultural validity of the Beery VMI by establishing whether there was a difference in children's visual-motor integration performance between Singaporean and American preschoolers as well as if there were any differences in the visual-integration skills of three ethnic groups residing in Singapore: Chinese, Malay, and Indian preschoolers. This would provide insights about the use and applicability of the Beery VMI in cross-cultural contexts like Singapore. The Beery VMI 5th edition was completed by 385 preschoolers (mean age = 63.3 months) from randomly selected schools in Singapore. The Beery VMI scores of the Singaporean preschoolers were compared with the standardization norms from the United States. The results indicated that there were statistically significant differences between Singaporean and American preschoolers, Chinese and Malay preschoolers from Singapore, and Chinese and Indians preschoolers in Singapore. Lim et al. (2015) concluded that preschool-age children "from different cultural and ethnic groups had different VMI performance. Certain cultural beliefs and practices may affect VMI performance" (p. 213).

Brown et al. (2011) investigated the convergent validity between the Beery VMI and the Full Range Test of Visual Motor Integration (FRTVMI) amongst three groups of participants: 73 children aged 5–10 years (mean age 7.5 years, SD = 2.20), 19 adolescents aged 11–17 years (13.1 years, SD = 2.16), and 61 adults (mean age 31.82 years, SD = 11.20). The Beery VMI and FRTVMI scores for the three participant age groups were all significantly correlated. "Overall, the DTVM and the FRTVMI exhibited large levels of convergent validity with each other, indicating that the two tests appear to measure similar visual-motor integration constructs" (Brown et al. 2011, p. 295).

Using the Rasch model, Brown et al. (2009a, b) inspected the construct validity of the Beery VMI 5th edition. The study involved 400 typically developing children from Victoria, Australia, aged 5–12 years of age. The findings indicated that none of the Beery VMI items "exhibited RMM misfit due to goodness-of-fit mean square (MnSq) infit statistics and standardised z (ZStd) scores being outside the specified acceptable range" (Brown et al. 2009, p. 393). However, Beery VMI item nine demonstrated differential item functioning based on gender. Several of the Beery VMI items were found to have similar levels of difficulty. For example, VMI items 26, 27, and 29; items 18, 22, and 24; and items 4, 5, and 11, were found to have the same level of challenge and this may indicate that some of the items may be redundant. Similarly, the Beery VMI scale item logit measure order did not correspond to that presented in the Beery VMI manual. "Theoretically, the VMI items are developmentally ordered; however, this ordering was not mirrored by the item logit difficulty scores obtained" (Brown et al. 2009, p. 393). In a second study involving the same group of participants, Brown et al. (2009) explored the factor structure of the Beery VMI. The factor analysis results indicated that the Beery VMI generated six viable factors thus demonstrating multidimensionality rather than one overall visual-motor integration factor, in other words, unidimensionality.

Wuang and Su (2009) investigated the measurement properties of the Beery VMI using

Rasch analysis. A sample of 454 children with an intellectual disability aged 4–12 years of age completed the Beery VMI. The following features were examined: unidimensionality, item fit to the model, differential item functioning, item targeting, and discriminative validity. Wang and Su (2009) generated a nine-item version of the Beery VMI that was considered valid and reliable for use with children presenting with an intellectual disability instead of the current 30 item version. However, changes to the Beery VMI items can only be made by the test's authors and the copyright holders.

One of the primary strengths of the Beery VMI is its long history of psychometric validation and reliability studies starting in 1967. It is also easy to use, provides detailed scoring guidelines, and has been standardized on a large sample group. It is widely used internationally and can be administered, scored, and interpreted by a number of health and education professionals. This adds to the versatility and applicability of the Beery VMI as a clinical assessment and research measure. However, one limitation noted by McCrimmon et al. (2012) about the most recent edition of the Beery VMI relates to its “lack of current validity and reliability research. Although the newest edition is based on a strong foundation, much of the psychometric data reported in the manual pertain to previous versions” (p. 592). Therefore it would appear that more current psychometric studies need to be completed. It is recommended that the Beery VMI would be a useful, informative, and appropriate assessment to use with children and adolescents presenting with ASD.

Clinical Uses

“The Beery VMI is designed to assess the extent to which individuals can integrate their visual and motor abilities (eye-hand coordination)” (Beery and Beery 2010, p. 1). The Beery VMI, VPT, and MCT can be used for a variety of clinical purposes in a variety of settings with a variety of client groups. As well, the Beery tests can be used on their own or as part of a larger battery of tests. It is often used by psychologists, occupational

therapists, educators, neurologists, pediatricians, speech/language pathologists, physiotherapists, optometrists, rehabilitation medicine physicians, low-vision specialists, and others to assess children and adults. The Beery VMI, VPT, and MCT can be used in acute care hospitals, rehabilitation centers, geriatric care centers, community health centers, private practice settings, early intervention centers, and primary and secondary school settings. The Beery tests have also been widely used to assess the VMI skills of variety of diagnostic groups including those with ASD (see section above). The Beery VMI provides standard scores for children aged 2-years old, which is rare among psychological assessments. In addition, the Beery VMI is designed to be sensitive to developmental change making it useful in testing the effectiveness of interventions and within a Response to Intervention (RtI) framework.

The Beery VMI is often included as part of a comprehensive neuropsychological test battery or as part of a psychoeducational assessment battery completed by psychologists. Educators, psychologists, and occupational therapists often use the Beery tests when evaluating or screening preschool-age and school-age children presenting with known or suspected developmental delays or learning disabilities. For example, the Beery VMI is frequently utilized in early intervention settings by therapists or by kindergarten teachers to screen children's VMI skills (Dankert et al. 2003). Occupational therapists will often use the Beery VMI, VPT, and MCT to assess children referred to them presenting with sensory-motor problem or printing/writing difficulties (Case-Smith 2002). Optometrists frequently use the Beery tests as part of an initial assessment that includes perceptual and VMI skills (Sorter and Kulp 2003a). Psychologists and occupational therapists might use the Beery tests in rehabilitation settings to assess the VMI abilities of adults who have sustained a traumatic brain injury or older adults who have had a stroke (Hall et al. 1996). “Through early identification, it is hoped that further difficulties can be prevented or remediated by appropriate educational, medical, or other interventions” (Beery and Beery 2010, p. 10).

The clinical purposes the Beery VMI, VPT, and MCT could be used for are establishing the baseline of a client's VMI skills (often done in the context of an initial assessment), assisting with the formulation of a client's intervention goals, monitoring a client's progress after receiving intervention/remedial services, or providing evidence to justify the need for a client to receive continued services (Sorter and Kulp 2003b). The Beery tests can also be used for research purposes such as evaluating the effectiveness of educational, psychological, therapeutic, or medical services provided to clients (Dawson and Watling 2000). For example, Pfeiffer et al. (2015) scrutinized the use of Beery VMI as a potential outcome measure for hand writing interventions with first and second grade primary school students. The study involved 207 students divided into two groups. The first group completed a formal handwriting program while the control group received standard programing. The two groups completed the Beery VMI pre- and post-completion of the handwriting and standard instruction programs. When the pre- and post-completion Beery VMI scores were compared, no significant difference was detected. Pfeiffer et al. (2015) suggests that the Beery VMI may not be the most appropriate outcome measure to uncover clinically significant or skill-related changes in handwriting remediation interventions involving school-age children.

Individuals diagnosed with ASD, Asperger's Syndrome (AS), and other related pervasive developmental disorders (PDD) often present with VMI problems (Baranek et al. 2005; Dowd et al. 2012; Duffield et al. 2013; Fournier et al. 2010; Fuentes et al. 2010; MacDonald et al. 2014; Mayes and Calhoun 2003a; McPhillips et al. 2014; Novales 2006; Volker et al. 2010). "ASD evaluations need to include assessments of visual-motor control" (Beery and Beery 2010, p. 119). Numerous studies have indicated that the VMI skills of individuals with ASD and AS are often below average. For example, Volker et al. (2010) assessed the VMI skills of 60 children with high-functioning autism spectrum disorders (HFASDs) and 46 typically developing children using the *Bender Visual-Motor Gestalt Test Second Edition*

(BG-II) and Beery VMI. After statistically controlling for IQ, the HFASD group scored significantly lower than the typically developing group on the BG-II and Beery VMI with greater *motor* involvement. In another recent study, Green et al. (2016) examined the visual-motor integration skills of individuals who presented ASD. An all-male sample consisting of two contrasting groups were recruited into the study: 56 participants with ASD (ages 3 to 23) and 36 typically developing participants. Both groups completed the Beery VMI. The findings indicated that the two groups were significantly different in relation to their visual-motor integration skills as measured by the Beery VMI.

McDonald (2013) compared the visual-motor skills of children presenting with HFASDs. Ninety children with HFASD and 52 typically developing children completed the BG-II using the KOPPITZ-2 scoring system and the Beery VMI. In addition, a subsample of 33 matched pairs was analyzed to examine potential visual-motor differences between groups, while controlling for age, gender, ethnicity, parent education, and verbal ability. McDonald (2013) reported that the children presenting with HFASD had significantly lower scores on the BG-II and the Beery VMI, both samples scored significantly lower on the MCT than on the VPT, and a moderate level correlation was obtained between the BG-II and the Beery VMI composite score. These results are similar to those reported by Volker et al. (2010) and Schlooz and Hulstijn (2012).

In a study by Kimberly (2014), 45 participants between the ages of 8 and 14 years of age completed the forty-five participants completed the BG-II, Beery VMI 5th edition, *NEPSY Second Edition, Test of Visual Perceptual Skills-3, Navon Task, Kaufman Test of Educational Achievement, Second Edition, Kaufman Brief Intelligence Test, Second Edition, Behavior Assessment Scale for Children, Second Edition, and Autism Spectrum Screening Questionnaire*. The sample was composed of 22 males with autism spectrum disorder and 23 were typically developing. Kimberly (2014) found that there were no significant differences between the two groups on the BG-II, Beery VMI 5th edition, *Test of Visual Perceptual Skills-*

3, and *Navon Task*. However, students diagnosed with ASD have poorer performance on the *NEPSY Second Edition*. Regression analyses for visual-motor integration indicated the best predictors for the Beery VMI 5th edition was the *Test of Visual Perceptual Skills-3*. It also determined that the Beery VMI 5th edition was predictive all areas related to academic achievement (Kimberly 2014).

Lopata et al. (2007) assessed the gross motor, fine motor, and visuomotor skills of 17 boys, 6–13 years old, with AS. Statistically significant deficits were found for the sample's scores on three types of motor skills. Using the WRAVMA, Novales (2006) assessed the VMI skills of 63 children and adolescents with AS ranging in age from 8 to 18 years (with a mean age of 11 years, 2 months) and found that “individuals with AS performed significantly more poorly on most measures of visual-motor ability when compared to neurotypically developing peers” (p. 2260). In a similar study, Mayes and Calhoun (2003a, b) assessed 63 children with autism ranging in age from 6 to 15 years using a number of IQ tests and found that the children had significantly low scores VMI skills. Therefore, the Beery VMI, VPT, and MCT can play an important role in the assessment of and intervention planning for individuals presenting with ASD, AS, and PDD. In summary, “the primary purpose of the Beery VMI is to help identify, through early screening, significant difficulties that some children [and adults] have integrating, or coordinating, their visual-perceptual and motor (finger and hand movements) abilities” (Beery and Beery 2010, p. 10). The Beery VMI is recommended as an appropriate assessment for use with children, adolescents, and adults presenting with ASD.

Visual-Spatial Ability

Madison, Madison, WI, USA

Definition

Visual-spatial ability is a broad term that emphasizes processes such as image generation, storage, retrieval, and transformation and includes a collection of skills in the areas of spatial relations, visualization, visual memory, closure speed, and spatial scanning (Mather and Wendling 2005). Because visual-spatial ability is a multi-dimensional construct, it is possible for an individual to have a relative strength in one area of visual-spatial ability (e.g., visual memory of objects) and a relative weakness in another (e.g., spatial relations; Mather & Wendling).

The visual environment can be organized into a meaningful whole through visual perception (Grieve 2000). Visual perception of an object requires the integration of several features, such as color, depth, separating shapes and objects from their background, and form constancy. Visual object recognition involves integrating visual perception with previous knowledge of known objects. Spatial ability, on the other hand, involves the integration of visual scanning of space, mental representation of the relative position of one's body parts in space, ability to perform the necessary movements for a task, and understanding of the topographical environment (Grieve 2000).

Visual-spatial ability is an area typically measured as part of neuropsychological examinations and may include the assessment of perceptual skills, constructional skills, and spatial awareness (Sattler and Hoge 2006). The

Perceptual Reasoning Index on the Wechsler Intelligence Scale for Children, Fourth Edition, which is comprised of the Block Design, Picture Concepts, Matrix Reasoning, and Picture Completion subtests, offers a broad measure of graphomotor, spatial, and visual scanning abilities (Sattler & Hoge). An example of a test that measures visual-motor perception is the Bender-Gestalt II. This test includes 16 stimulus cards that each contains a line drawing. Test takers are asked to copy each drawing on a blank piece of paper. A 5-point rating scale is used to score each item, and age-based standard scores are available for the measure (Sattler & Hoge). Another example is the Beery-Buktenica Developmental Test of Visual-Motor Integration, Fifth Edition (Beery VMI-Fifth Edition). This assessment includes 30 items that incorporate spontaneous drawing and copying designs from the stimulus book. Each item is scored as either a 0 or 1, and age-based standard scores can be calculated (Sattler & Hoge).

Historical Background

Components of visual-spatial ability, such as object perception and measuring basic properties of vision, have been researched by psychologists since the nineteenth century (Goldstein 2005). As behaviorism and its emphasis on observable behavior, rather than mental processes, became more prevalent in the first half of the twentieth century, less attention was paid to studying cognition. However, the field of psychology returned to an interest in mental processes later in the twentieth century (Goldstein 2005). Modern technology, such as brain imaging techniques, has allowed researchers to directly measure physiological activity related to cognition, including visual-spatial processes.

Current Knowledge

Neuroimaging research has found some overlap in brain activity during processes that involve visual

perception and visual imagery (Sternberg 2006). This research provides support for the functional-equivalence hypothesis, which states that, even though visual perception and visual imagery are not identical, they are functionally equivalent (Sternberg 2006).

Research findings have also indicated that visual and spatial imagery may be mentally represented differently (Sternberg 2006). Visual imagery is the use of images that represent characteristics such as shape and color, whereas spatial imagery represents characteristics such as depth, distance, and orientation.

Researchers have also examined how visual-spatial skills develop across the lifespan. Basic spatial understanding, including skills such as spatial visualization, begins to develop in children at a young age (Sternberg 2006). Spatial visualization refers to the capacity to orient oneself in one's surroundings and to mentally manipulate images of objects (Sternberg 2006). From childhood through young adulthood, the speed of mental rotation increases. Object familiarity has also been shown to increase mental rotation speed. Middle-aged adults generally have slower mental rotation speeds than young adults but have similar response times for image scanning tasks (Sternberg 2006).

Studies have not generally found a strong relationship between visual-spatial ability and academic performance, although some studies have found evidence of an association between visual-spatial ability and math performance (Mather and Wendling 2005). Performance on visual-spatial tasks has been shown to be influenced by speed, attention, motivation, working memory, and visual-motor coordination (Mather & Wendling). Research has found that visual sensory impairment can affect the perception and storage of visual cues, which contribute to visual-spatial ability (Baum and Katz 2010).

Future Directions

Current research on cognition, which includes visual-spatial ability, has emphasized an interdisciplinary approach to cognitive neuroscience

and has utilized brain imaging techniques to examine relationships between particular brain structures and specific cognitive processes (Goldstein 2005; Sternberg 2006). It is likely that these trends will continue and further contribute to researchers' understanding of visual-spatial ability.

Vocabulary is a set of words that a person knows. Typically, vocabulary is described as receptive and expressive. Receptive vocabulary refers to the words that are understood by a person, typically assessed by having the person point to a picture that is named. Expressive vocabulary refers to the words that a person can produce and is typically assessed by showing the person a picture and having them name the word depicted. Individuals with autism may use speech, sign, typing, or pointing to picture symbols to demonstrate their expressive vocabulary skills. People with autism may have vocabulary skills that are within the normal range of functioning or may have an impairment in one or both types of vocabulary.

Definition

Vocalizations are sounds produced by children before they learn to talk. For children with ASD, vocalizations may continue to be used throughout the life span, particularly if spoken language does not develop. Vocalizations can be divided into two categories: speech-like and nonspeech. Speech-like vocalizations include consonant and vowel sounds (e.g., baba, daba) and are often referred to as babbling or cooing. Nonspeech vocalizations are natural, vegetative sounds that do not resemble speech, such as crying, laughing, burping, as well as uncommon sound productions such as high-pitched squeals and low-pitched growls. A higher frequency and longer persistence of atypical vocalizations has been found to be present in children with ASD and in infants at high risk for the syndrome, before spoken language emerges.

Definition

A vocational evaluator is a professional whose goal is to help people match a career path to their interests, abilities, knowledge, personality, and skills. The evaluator's focus is to help integrate their clients into the workplace. The evaluator minimally holds a bachelor's degree with vocational evaluation specialization. Evaluators typically work in settings such as hospitals, schools, public agencies, and independent living centers and are sometimes in private practice. A certified vocational evaluator (CVE) has received national certification by the Commission on Certification of Work Adjustment and Vocational Evaluation Specialists (CCWAVES).

When evaluating clients on the autistic spectrum, the vocational evaluator will use a variety of instruments. These will provide information about the client's medical, psychological, social, vocational, educational, economical, and cultural history and abilities. The evaluator may assess such areas as being able to understand socially appropriate behaviors, the quality of communication skills, functional academics, and problem-solving skills. The evaluator will also look at the client's work-related behaviors, such as the ability follow directions and to complete tasks successfully, maintain an appropriate rate of work, follow rules, stay on task, and complete multistep

assignments. The outcome of the evaluation is a comprehensive report containing specific recommendations. This report can be used to guide the client and/or counselor in developing appropriate client employment goals.

Vocational Rehabilitation Act of 1973

Oren Shtayermman
New York Institute of Technology Mental Health Counseling, Old Westbury, NY, USA

Definition

The Vocational Rehabilitation Act of 1973 Title V was put in place to correct the problem of discrimination against people with disabilities in the United States. Affirmative action programs were established in Title V, Sections 501, 502, 503, and 504. Individuals who qualify as having a disability have experienced discrimination both because of negative attitudes in regard to their ability to be an effective employee as well as the physical barriers at work facilities. The Title V of the Vocational Rehabilitation Act requires private employers with federal contracts over \$2,500 to take affirmative action to hire individuals with a mental or physical disability. While this means that employers must make reasonable accommodations for disabled employees, it does not mean they must hire unqualified individuals. There are

additional sections of the Act that provide vocational counseling, training assistance, and job placement for individuals with severe disabilities.

In the context of the Vocational Rehabilitation Act, the term “disabled individual” means “any person who (1) has a physical or mental impairment which substantially limits one or more of such person’s major life activities, (2) has a record of such impairment, or (3) is regarded as having such an impairment.” This definition is closely related to the definition provided by the Americans with Disabilities Act.

The Vocational Rehabilitation Act does not require employers to hire or retain a disabled person if the individual has a contagious disease that poses a direct threat to the health and safety of others, and the individual cannot be accommodated. Also, employment is not required if the disability prevents the individual from being able to perform a required part of the job or if the individual would be considered unqualified for the job regardless of their disease or disability.

Vocational Training

Definition

Vocational training is a form of education that is practically oriented. Individuals who are enrolled in vocational training are learning skills specific to a particular occupation or job. These occupations tend to be manual jobs by nature and are in the mechanical arts or some other form of industry, agriculture, or trade. The education is less academically oriented with an emphasis upon practical skills and apprenticeship work. The students learn the trade by doing supervised work. Extensive practical experience is given in lieu of learning theory, technical knowledge, or following a liberal arts education.

Historical Background

The history of vocational training is as long as humans have been involved in organized activity for survival and commerce. The training of individuals was conducted by the family, tribe, or later village members. Often, young children of impoverished families were put in the care of skilled craftsman or better-educated individuals as a way of the child to learn vocational skills as an apprentice or indentured servant. This insured both the child's and the family's survival.

During the later part of the medieval and into the Renaissance periods, Western Europe would see the rise of the university which led to a new

educational and economical structure and system. The impact of the rise of the university would be upon the class system. No longer would only the nobility be able to read and write, but a new class of citizens would have this skill set. A university education led to new jobs in the economic structure. A university education began to be a viable path to economic survival for an individual. Apprenticeships were now not the only way to learn vocational skills and gain employment.

The industrial revolution also contributed to the change in the way individuals learned job skills. The economic structure shifted from cottage-based industries where family members taught children how to work and create products to be sold outside of the home and to mass-produced products manufactured in factories to be sold to the public on a large scale. The creation of the assembly line method meant that individuals went from being skilled craftsmen responsible for the creation of a product from start to finish to workers who specialized in the completion of one aspect of the overall product. This was often repetitive and dangerous work. The industrial revolution also shifted where the population lived. Prior to the industrial revolution, the greatest proportion of the population lived in agrarian centers or sparsely populated villages surrounded by farms. With the advent of the factory, the population shifted to large urban centers living near the factories where they were employed. "Improvements in transportation and communication - roads, canals, and railroads - brought communities closer together, stimulating the exchange of goods and services as well as the growth of cities" (Barlow 1976, p. 31).

There was no coordinated effort to begin vocational training in the United States or abroad. An educational system was in its nascent stage in the United States. Each state was responsible for the creation of an educational system since there were no constitutional provisions for a national educational system. Horace Mann, Secretary of the Massachusetts State Board of Education (1837–1849), would be credited with the revolutionary concept of free, public, universal education. The concept of the common school was beginning to take root in the country. The

common school was what we would refer to as primary education in today's terms. Secondary education was a radical idea, and the notion of public tax dollars being spent to fund schools was highly controversial. High schools, which would become the home base for vocational training, were rare. According to Barlow (1976), there were only 60 high schools in the entire country by 1850. The Manual Labor Movement, the Hampton Institute, the Morrill Act, and the Kalamazoo Case all converged during this time period to influence the formation of vocational education.

The Manual Labor Movement was led by farmers, mechanics, and artists. In England, in the early nineteenth century, the Mechanics' Institute was formed. It attempted to "regain the educational values lost with the coming of the factory system" (Barlow 1976, p. 32). During the 1820s, the Franklin Institute, the Maryland Institute for the Promotion of Mechanic Arts, and the Ohio Institute of Cincinnati were established in the cities of Philadelphia, Baltimore, and Cincinnati, respectively. These institutes all had reading rooms, libraries, public lectures, cabinets of models and apparatuses, and day and night schools, among their offerings. Educational reformers such as Emma Willard, Catherine Beecher, Mary Lyon, and Ellen Richards began to question the prevailing notion that the woman's place was in the home. Lyon established Mount Holyoke Female Seminary in 1837. Women began to attend postsecondary training, and Elmira College granted the first college degrees to women in 1855 (Barlow 1976). The home economics movement was born during this time period which was a precursor to independent living skills training for individuals on the autism spectrum.

The Hampton Institute is the acknowledged beginning of the Trade School Movement. After the Civil War, a great debate raged in the country regarding whether freed Negroes should have a classical education or an industrial education. As early as 1853, Frederick Douglass advocated for industrial schools for Negroes, while Harriet Beecher Stowe provided financial backing for either an industrial school or a classical education

for freed Negroes. General Samuel Chapman Armstrong commanded a regiment of Negro soldiers during the war and worked as the superintendent of education under the Freedmen's Bureau. He organized the Hampton Institute for the training of Negroes in skilled manual labor. Armstrong viewed a skilled Negro labor force as essential to the reconstruction of the South post-Civil War, and he felt that a liberal education was essential to improving the Negroes social status (Barlow 1976). The Hampton Institute offered vocational training in trades, many of which are still offered in vocational training centers to this day (e.g., plumbing, carpentry, mechanics, upholstery).

The passage of the Morrill Act in 1862 made it possible for states to establish universities. The idea was the brain child of Jonathon Baldwin Turner who believed that society was composed of two classes: a professional and an industrial class. His dream was to establish an industrial university in each state. To fund his dream, he proposed that federal aid be generated through the sale of public lands. Farmers in his home state of Illinois enthusiastically supported the idea. "The act of donating public lands to establish colleges for the benefit of agriculture and the mechanical arts called for land grants to states based on their representation in Congress—30,000 acres for each senator and representative" (Barlow 1976, p. 38). President Lincoln signed the bill into law on July 2, 1862.

The Kalamazoo case represented a major turning point in education and the establishment of vocational training in high schools. The majority of the educational reform thrust was focused upon primary school or the common school as it was called. Students were not expected to receive a public education beyond the 8th grade. In 1874, the Michigan Supreme Court heard the case where citizens from Kalamazoo brought forth a suit against the school districting disputing the right to collect taxes to support local public high schools. The court ruled against the plaintiffs finding an inconsistency between the provision of primary schools and state universities and forcing parents to find private education to prepare students for higher studies. This provided the right

to equal access to higher education for all. It established the right of school districts to levy taxes to support high schools. However, it would not be until well into the twentieth century that vocational training would become a part of the high school curriculum (Barlow 1976).

In the United States after the American Civil War, Abner Flexner began a crusade to reform the medical training of doctors and later higher education as a whole. Doctors were primarily trained through apprenticeships with no standards for their training and no standards for the people who trained them. Virtually anyone could call themselves a doctor, and any institution could call themselves a medical school (Starr 1982). Flexner led the reform of not only medical schools but university education in general. This led to the closing of over half of the medical schools across the country. It also led to the questioning of many groups as to whether or not they were indeed a profession and what a profession was in general. Did they as a group have a unique skill set, an ethical code, and a transmittable knowledge base? Having a transmittable knowledge base distinguished a profession from a trade. It also meant that professionals went onto higher education through the nation's system of colleges and universities, whereas skilled craftsman learned their craft through vocational or trade schools.

Rationale or Underlying Theory

The rationale for training individuals with ASDs specifically to work is that many have a desire to work and be productive members of society. Otherwise, society must support these individuals who have an average life expectancy that is well over 70 years of life. Although no specific epidemiological data are available on the unemployment rates of people with ASDs, anecdotal evidence suggests their unemployment rate is around 90% (Gerhardt 2011, personal communication). The costs of not providing vocational training are staggering from a fiscal and emotional perspective. Tax credits are available to employers who train and hire individuals with disabilities.

Goals and Objectives

The goals of vocational training for individuals with ASDs are to match the interests, aptitudes, and job availability with the individual in order for the person to work in a setting with the highest level of independence and community integration possible. This means the vocational goals must be individualized. In addition to specific job skills, the objectives should include the adoption on prevocational skills that will guarantee employment success. These objectives should include demonstrating appropriate dress for employment; good hygiene; the ability to cook and feed one's self before, during, and after working; and the ability to transport one's self to and from work.

Treatment Participants

Treatment participants are those individuals on the autism spectrum who have a desire to learn how to work.

Treatment Procedures

Vocational training is not a treatment *per se*. Rather, it is an educational approach that focuses upon teaching skills that are directly related to a particular occupation. The training is practical in nature and focuses upon how to complete a task or job. This differs from professional training where the education is less directly related to tasks performed by a specific occupation. Professional training often teaches theory, ethics, and how to think and problem solve. These skills are applied generally to a wide variety of work-related situations. Vocational training, by contrast, teaches how to complete specific tasks.

Prior to engaging in vocational training of an individual with autism, one must complete a thorough evaluation of the person's strengths, areas of difficulty, interests, and aptitudes. For younger individuals, the evaluations can be conducted through the local school district. IQ tests and assessments of reading, writing, and math ability are conducted on a triennial basis as

a part of the special education system and are part of writing an Individualized Education Plan (IEP) under the Individuals with Disabilities Education Act (IDEA). Under IDEA, students beginning at age 14 should have a transition plan written describing the goals for the student and how the student will reach those goals. The goals in the transition plan typically are focused upon vocational training or postsecondary education. The evaluators will need to conduct vocational assessments and examine things like fine motor skills, especially if the individual is interested in an occupation that involves a great deal of eye-hand coordination. An occupational therapist who is a part of the school-based support team can conduct such an assessment. Part of the occupational therapist's evaluation may include an assessment of assistive technology. Functional assessments for assistive technology are not covered by IDEA. These assessments are a part of Assistive Technology Act of 2004, P.L. 108-364; 29 U.S.C 3001 et seq.

Older individuals with autism can receive vocational assessments through state offices of vocational and rehabilitative services. The state office of vocational rehabilitative services or office of persons with developmental disabilities may subcontract these services to private not for profit social service agencies. The exact names of these offices vary by state. Consequently, keyword searches for these offices require the use of a variety of synonyms. These state services will not only evaluate the individual through the use of paper and pencil or computerized aptitude tests and interest inventories, but they will conduct observations of the individuals in work settings to evaluate the goodness of fit between the individual and the job setting. Working with the individual employees of the office of vocational and rehabilitative services will develop an Individualized Plan for Employment (IPE) also known as an Individualized Employment Plan (IEP) which is distinct and separate from an Individualized Educational Plan (IEP) under IDEA. The Individualized Plan for Employment (IPE) is a document that outlines the plan for the individual seeking employment through a series of behaviorally specific goals with fixed deadlines

and outcomes. It will specify the type of training he or she will receive and who will provide the services and where those services will take place. This IPE can help the person obtain assistive technology in order to attend a community college. The IPE can also prescribe other types of supports that the person will need in order to be successfully employed. The other types of support can be learning to drive a car or travel training on mass transit, so the individual can get to work or to attend resume writing workshops or job interview clinics.

After the individual has been evaluated and assessed and his or interests and aptitudes have been determined, then an assessment of the current and future job markets should be conducted to insure the long-term employment of the individual with autism. One excellent source of information is the US Department of Labor, Bureau of Labor Statistics. This department publishes a number of documents which are free to the public. One document in particular, the *Occupational Outlook Handbook* (OOH), is available on a yearly basis. This report informs readers the type of training and education needed by occupational title, the expected earnings of individuals in a vocation, the expected job prospects, a description of what workers do in an occupation, and the working conditions someone faces with a particular job title.

Once an individual with autism has had their aptitudes, abilities, and vocational interests assessed and those have matched with the employment outlook for a particular vocation, then the individual must decide where to obtain the vocational training. There are three general places to obtain training for future employment: traditional vocational training programs, supported academic programs, and comprehensive transition and postsecondary programs (CTPs). Traditional vocational training programs may begin in high school. Some are integrated into the standard high school curriculum. Others are structured as alternative high schools. A third permutation of the traditional vocational training center is a county or municipal training center that draws from a larger catchment area than the local high school. This third permutation may include

students who are receiving postsecondary training, and these training programs often work with state offices of vocational and rehabilitative services. A final option for traditional vocational training is a private vocational training or “tech” school. The final option is not one that an individual on the autism spectrum should have to pursue. Private vocational training centers charge a tuition, and their students should be eligible for federal student aid. However, students on the autism spectrum should be entitled to vocational training through state offices of vocational rehabilitative services or state offices of persons with developmental disabilities. They do not need to pay tuition for vocational training.

Most people are familiar with the variety of occupations available to students who attend vocational training. The most common occupations that readily come to mind are automotive repair, plumbing, carpentry, electrical repair, cosmetology, culinary arts, clerical skills, and retail. However, there are a number of other occupations that do not readily come to mind. Some vocational centers offer veterinary assistant, small animal care, physical therapy and occupational therapy assistant, digital photography, and personal trainer certificate programs. Many individuals on the autism spectrum who are higher functioning have an acute interest in computers. However, many do not see the utility in obtaining a liberal arts degree in computer science, computer engineering, or computer graphics. They refuse to take the English or humanities courses that are required to fulfill the degree program because the course is not directly related to working with computers. Many vocational training centers will offer certification courses in computer programming, networking, and/or repair. Others will offer certification courses in specific software applications. Data entry for individuals on the autism spectrum, who are interested in this occupation, is often a good choice for those individuals who prefer predictability and routine. Some businesses have found that individuals on the autism spectrum who are in data entry fields have higher accuracy rates than their neurotypical peers (Bennett 2009). Consulting the *Occupational Outlook Handbook* for fields that have the most

projected openings will help maximize the chances of the person becoming employed.

The second place or type of program where higher functioning individuals on the autism spectrum can receive vocational training is through supported academic programs at colleges and universities. The training one receives at college or university is less directly related to a specific vocation. The notion is that the liberal arts education is meant to teach an individual how to think and problem solve. It is up to the individual to apply what he or she has learned to the work environment. Experiential learning through service learning programs or internships is the most direct form of vocational training at colleges or universities. Supported academic programs at colleges and universities are charged with insuring that the institution is in compliance with the Americans with Disabilities Act. This often occurs through the college’s Disabled Student Services (DSS) office (although some colleges are beginning to offer programs specifically designed to support higher functioning individuals on the autism spectrum). This office is charged with insuring that the individual with a disability is not denied access to or the benefits of the university solely on the basis of his or her disability. The student must be “otherwise qualified” to attend the university which means they must have the intellectual ability to meet the academic demands of a degree program. The DSS office will assist the student with a disability by either altering the environment (e.g., providing notetakers or allowing testing in alternative venues) or by modifying the behaviors or the skills of the student (e.g., teaching organizational skills or providing stress management workshops). The range of remedial and supportive services is wide due to how the organization interprets ADA. The DSS offices are generally very good at providing reasonable accommodations that involve academic interventions. Colleges are less adept at providing accommodations in the social or sensory integration realms.

Many higher functioning individuals on the autism spectrum are quite comfortable with the structure of the academic demands of college

courses. Individuals on the autism spectrum have difficulty, not with the academic demands but rather with the independent living, executive functioning, and social skills demands of living in a university environment (VanBergeijk et al. 2008). In order for universities to be successful places for vocational training for individuals with ASDs, they must provide the structure and scaffolding necessary to address these deficits. Otherwise, students with ASDs will not be able to access the benefits of the university degree because of the nature of their disability. Colleges must target students with ASDs to also participate in resume writing, interviewing, and job search workshops in order for these students to be successfully employed. The Health Center at George Washington University and Thinkcollege.net are two sources that are helpful in identifying supported academic programs for students with a variety of disabilities. The third place students with autism can receive vocational training is a Comprehensive Transition and Postsecondary program (CTP). CTPs combine aspects of traditional vocational training programs and supported academic programs. This hybrid model focuses upon vocational, independent living, social, and academic skills training. These programs are more individually tailored and do not necessarily result in a college degree. Their goals are to either transition the individual into the world of work and independent living or transition the individual with an intellectual disability into a degree-bearing program full time. A CTP can last longer than a traditional 4-year degree program. Most CTPs have four key components: (1) supported employment and work skills training, (2) adult life skills training (e.g., financial management, grocery shopping, laundry, and home maintenance), (3) social and personal relationships counseling and training, and (4) encouraged social involvement in the community. The best practices of CTPs are (a) using group modality, (b) involving the family, (c) developing community partnerships, (d) taking a long-term approach by following up with graduates, and (e) ongoing evaluation. Involvement of the family distinguishes this model from supported academic programs and traditional vocational training

programs where the expectation is that the family will generally not be involved in the process.

There are two subtypes of Comprehensive Transition and Postsecondary Programs (CTPs), and the distinction is important. The first subtype is a college-affiliated CTP. Generally, college-affiliated CTPs are either not for profit or for profit private social service agencies that are based out of an apartment complex or group housing situation. They are not formally a part of a college or university. However, they may have a memorandum of understanding with a local community college which outlines the relationship between the agency, the college, and the students with a variety of disabilities, not just autism spectrum disorders. College-affiliated CTPs are ideal for individuals on the autism spectrum who have difficulty generalizing independent living skills across environments. Individuals are taught independent living skills in their own apartments. The second type of CTP is the college-based CTP. College-based CTPs are an official program or department of the college or university and draw upon its infrastructure. The distinction between the two subtypes is important in terms of Federal Financial Aid. Students with intellectual disabilities who are enrolled in a college-based CTP that is recognized by the US Department of Education are eligible to complete the Free Application for Federal Student Aid (FAFSA). By completing the FAFSA, students with intellectual disabilities including autism may receive Pell Grants, Federal Supplemental Education Opportunity Grants (FSEOG), and student work study monies. Students with intellectual disabilities who are enrolled in college-affiliated CTPs are *not* eligible for federal financial aid.

Efficacy Information

Vocational training in a postsecondary environment is critical to employment for people with any type of disability and especially for those on the autism spectrum. Recall the unemployment rate for individuals with ASDs is around 90%. Obtaining any type of postsecondary training

significantly increases the probability that the person with disabilities will be employed. “In fact, employment rates for people with disabilities demonstrate a stronger positive correlation between level of education and the employment rate than is seen in statistical trends for the general population. . . for individuals with disabilities a university education is highly correlated with vocational options and financial success” (Wehman 2001, pp. 248–249).

Outcome Measurement

The ultimate outcome for individuals on the autism spectrum is that they are employed in a competitive work environment with no supports and they are able to fully support themselves. However, there are many other outcomes between this outcome and unemployment and being fully dependent upon others for survival. If competitive employment is the apex of an employment pyramid, then the next level of independence is customized employment. According to Gerhardt (2009), customized employment is a “. . . highly specialized derivative of supported employment, supported employment tends to match individuals with previously existing jobs in the community. Customized employment. . . works to create highly individualized, yet economically viable, jobs through active employer negotiation. . .” (p. 20). Supported individualized placements are a third possible employment outcome where individuals with ASDs are placed in an existing job and are supported by a job coach who provides on the job training. Slowly, the supports of the job coach are withdrawn, while the individual develops natural supports in the environment. A variant of this model is the enclave or cluster model according to Gerhardt (2009). In this model, a job coach works with a small group of people with disabilities at a community location. A permutation of the enclave model is the work crew approach, where mobile work crews provide contracted services across a geographic area (e.g., cleaning services or lawn care). Entrepreneurial models involve 1–2 individuals with ASDs who develop a business based upon their own interests.

An example of a successful entrepreneurial model started by individuals with ASDs is an auto detailing business. The last two employment outcomes for people with ASDs provide the least integration. Day habilitation programs focus upon “pre-employment” skills and activities of daily living to individuals living in congregate care. There is little risk of being fired at this type of employment facility because of behavioral issues. “The least integrated work setting for individuals with ASDs is the sheltered workshop where the focus is solely upon providing enclave like employment experience for adults with developmental disabilities” (Gerhardt 2009, p. 23).

Qualifications of Treatment Providers

Traditional vocational training centers are often operated by local or county school districts and receive their auspice from either the state office of education or a state office of vocational and rehabilitative services. Supported academic programs and college-based CTPs operate under the auspices of a college or university. The college or university reports to the state office of education and also the Middle States Commission on Higher Education. Colleges must routinely go through a reaccreditation process through the Middle States Commission on Higher Education. Before applying to a college and enrolling in a supported academic program or college-based CTP, the consumer must insure the college is accredited. Otherwise, the degree or certificate granted may be worthless. College-based CTPs also are under the auspices of the US Department of Education if their students receive federal financial aid. College-affiliated CTPs are not necessarily regulated and do not report to a specific government agency or college administrative office. They are often private businesses.

In terms of the qualifications of instructional personnel at vocational training center, instructors should have the highest levels of certification possible in their trade. Support personnel in disabled student services offices will have a variety of related bachelor’s degrees, and some will have master’s degrees in fields such as higher

education administration, counseling degrees, and human resources. Because comprehensive transition and postsecondary programs provide a wider range of support services, the range of professional qualifications of the staff will be greater. The qualifications at a minimum should be a bachelor's degree in a helping or education profession. Many will have master's degrees in social work, education, special education, assistive technology, occupational therapy, nursing, etc. Key administrative personnel should have doctorate degrees in education, social work, vocational and rehabilitative sciences, and occupational therapy.

Voice Output Communication Aids

Vannesa T. Mueller

Speech-Language Pathology Program, University of Texas at El Paso College of Health Science, El Paso, TX, USA

Definition

Voice output communication aids (VOCAs), also called speech-generating devices (SGDs), are high-tech, augmentative, and alternative communication (AAC) devices that produce speech for an individual who has limited or no means to communicate orally. These AAC systems produce a synthesized or digitized voice for the user. A digitized voice is a live voice that has been recorded and played back. Synthesized voices (also known as text-to-speech engines) are those that are created by programs called speech synthesizers. Different algorithms are used to create synthesized speech. Some programs use a database of recorded speech and then divide the sample into individual phonemes or diphones (two phoneme combinations) which are then combined to form spoken words. Alternately, whole words can be stored and reproduced. The benefits of a digitized live voice are the naturalness and intelligibility of the voice output. The drawback is the time and effort required to record a voice to

capture every message an AAC user would like to speak. Synthesized speech is judged in terms of naturalness and intelligibility. In the past, synthesized voices sounded very robotic, but the field has made great strides in creating synthesized voices that sound more natural.

VOCAs come in many different shapes and sizes and with a variety of features. The BIGmack (distributed by AbleNet) is a single message switch which produces a digitized voice. When the user presses the switch, the device plays a prerecorded message such as, “I’m hungry.” The BIGmack is an example of a simple VOCA for an individual who either does not need or cannot use complex communication. The Maestro (produced by DynaVox) is an example of a VOCA on the other end of the complexity continuum. The Maestro is a dynamic device in which the user can combine symbols to form long messages. Messages can also be stored for more efficient access in the future.

VOCAs are used with a variety of individuals with speech and language impairments. Some populations include individuals with autism, Down’s syndrome, spinal cord injury, traumatic brain injury, aphasia, dysarthria, amyotrophic lateral sclerosis (ALS), cerebral palsy, and apraxia of speech.

Historical Background

Early AAC strategies in the 1970s for individuals with autism spectrum disorders (ASDs) focused heavily on the use of sign language. The use of visual symbols with individuals with ASDs began in the 1980s. The use of VOCAs is a relatively recent development in the field of AAC mainly due to the wider availability of the technology.

For more information on the history of the field of AAC, see the entries on Alternative Communication, Pictorial Cues, and Total Communication Approach.

Rationale or Underlying Theory

The rationale for using VOCAs is to provide an individual with a voice. Mirenda (2001) described

some additional advantages for the use of VOCAs. These include the ideas that “they have the potential to be easily integrated into everyday environments with unfamiliar people” (p. 146) and their use can “facilitate natural interpersonal interactions and socialization by virtue of the speech output they provide” (p. 147).

The rationale for using augmentative and alternative communication can be found in the term itself. AAC is first augmentative. The purpose for this type of intervention is to augment or supplement the speech an individual naturally possess. For some individuals, however, this intervention is an alternative form of communication. These individuals have no means of verbal speech and so need to implement an alternative form. AAC is the means by which these individuals communicate.

Goals and Objectives

The goal for the implementation of VOCAs as with other forms of augmentative and alternative communication (AAC) is functional communication. However, communication with AAC is excruciatingly slow as it has been estimated that an average AAC user communicates at approximately 15 words per minute (Foulds 1987) compared to 150–250 words per minute for speakers (Goldman-Eisler 1986). Therefore, rate of communication should not be expected to occur as fast as spoken communication for individuals who use VOCAs.

Treatment Participants

Any individual who has impaired communication is a candidate for AAC in general. Therefore, because communication impairments are a hallmark of autism spectrum disorders (ASDs) (Mirenda 2009), most individuals with ASDs are candidates for a total communication approach. Specifically for VOCAs, many individuals with more severe impairments do not use the more complex or powerful devices (Rispoli et al. 2010). Developmentally, the strategy for many clinicians has been to introduce picture symbols first and then transition the child to a VOCA when

they are “ready.” Cress (2010) suggests that it is “never too early to introduce VOCAs.” She states that a child can use AAC to affect the world and that simple VOCAs can be programmed as cause/effect toys.

Treatment Procedures

According to a review by Rispoli et al. (2010), the two main methods of introducing VOCAs are discrete trial training (DTT) and milieu teaching. When requesting was the communication goal, Rispoli et al. (2010) found that DTT was the most common method of instruction, while milieu teaching was common when the goal was social interactions and conversational skills.

Discrete trial training is a procedure used in Applied Behavior Analysis (ABA) approaches. During DTT, the professional and the child work for short periods of time in a structured setting. Five steps make up each trial:

1. Cue – The professional provides the child with a stimulus.
2. Prompt – The professional provides assistance to the child. Hand-over-hand assistance is provided during the early stages of learning the behavior and is slowly faded.
3. Response – The child provides a response to the cue.
4. Consequence – The professional provides praise or a reward for a correct response or indicates to the child if an incorrect response was given.
5. Intertrial interval – A 1–5-s interval is given before the next cue.

Milieu teaching techniques are used during the child’s everyday activities and are often considered errorless learning. For example, a child who uses a VOCA may express a desire to join a game other children are playing. The professional may help the child choose the correct message on their device such as, “Can I play too?”

See the encyclopedia entries in this volume for more information on these treatment approaches.

Efficacy Information

Van der Meer and Rispoli (2010) conducted a review of intervention studies which used VOCAs with children with autism spectrum disorders (ASDs). The studies reviewed were conducted between 1998 and 2009. Most of the studies (83%) employed a single-subject research design. There were no instances of a large group design using randomized control trials. Requesting was the most frequently targeted communication skill. The majority of the studies (78%) had positive outcomes for the targeted communication skill and were also classified as demonstrating conclusive evidence. The authors cautioned that although encouraging, not all studies reviewed demonstrated conclusive evidence and so the results should be interpreted carefully. Generalization or some form of follow-up was only included in a small number of studies demonstrating a need for further research in this area. Overall, VOCAs were shown to be a “potentially effective option for teaching communication skills to children with ASD” (p. 304).

Outcome Measurement

Because the goal of any AAC use is functional communication, the outcome measurement should be the same. Functional communication of course will be defined differently based on the cognitive skills of the individual and the type of AAC system that is in place.

Qualifications of Treatment Providers

AAC interventions are most typically introduced by a speech-language pathologist. Unfortunately, many speech-language pathologists do not report having adequate training or education in the field of AAC (King 1998; Marvin et al. 2003; Simpson et al. 1999), and a survey of education programs for speech-language pathologists has uncovered a need for better education in this area (Ratcliff et al. 2008). Although this is the case, speech-language pathologists are the best equipped of all

professionals who work with individuals with autism to provide intervention that includes AAC. A listing of speech-language pathologists who are certified by the American Speech-Language Hearing Association can be found on their website. A few short questions posed to the speech-language pathologist can reveal whether they are comfortable with the area of AAC.

Definition

Wait training is synonymous with teaching “tolerance for delay.” For example, some people with ASD may become restless and disruptive when they are told to “wait” after making a request. Or, they may have difficulty waiting for a future activity to occur. It is first necessary to identify the situations and conditions that will be the focus of wait training. Next, a defined wait period is selected, usually a short duration a person can comfortably tolerate and then increased gradually over time. In illustration, a child or adult may be unable to wait before eating at a favorite restaurant. Wait training in this setting would begin by informing the person that she/he will have to “wait to be called” to the table. Training can be supplemented with visual cues such as a small card showing a red circle (“wait”) on one side and a green circle (“go”) on the other side. When displaying the red side of the card, a parent or care

provider would praise the person for “waiting” or possibly allow her/him access to preferred objects such as a music source (iPod) or book throughout the wait period. When it is time to be seated in the restaurant, the person would be shown the green side of the card, praised again, and allowed to go to the table. This final step of wait training, gaining access to the highly preferred activity, is intended to reinforce the preceding sequence of behaviors, namely, entering the restaurant, sitting quietly, and remaining occupied until the meal begins. With routine training, visual cues and social reinforcement eventually can be withdrawn so that an initial “wait” instruction is sufficient. Of note, training someone to wait in one setting or under certain conditions may not extend to other settings and conditions unless similar training is implemented there.

Weak Central Coherence

Definition

The term “central coherence” refers to the “neurotypical” (NT, i.e., non-autistic) tendency to pull information together and process information in context, looking for the “big picture” and drawing out meaning, often at the expense of details. By contrast, “weak central coherence” refers to the tendency in ASD to attend to and remember details rather than global form or meaning.

Historical Background

The term “central coherence” was coined by Uta Frith in her influential 1989 book “Autism: Explaining the Enigma.” This drive for coherence, in Frith’s words, “pulls together large amounts of information” like the tributaries of a river, and “without this type of high-level cohesion, pieces of information would just remain pieces, be they small pieces or large pieces”

(p. 97). She hypothesized that the drive for coherence was weaker in people with ASD and suggested that this would make them *better* than neurotypicals (NTs) at some tasks. Together with Amita Shah, she demonstrated that people with ASD were better than IQ-matched comparison groups on the Block Design and Embedded Figures Tests, demonstrating facility in seeing the parts without being distracted by the whole picture.

The concept of weak coherence is reflected in Kanner’s first reports of autism as involving an “*inability to experience wholes without full attention to the constituent parts. . . A situation, a performance, a sentence is not regarded as complete if it is not made up of exactly the same elements that were present at the time the child was first confronted with it. If the slightest ingredient is altered or removed, the total situation is no longer the same and therefore is not accepted as such*” (Kanner 1943, p. 246). Kanner’s interest in global–local processing in ASD, and its relationship with insistence on sameness, is reflected in the title of his 1951 paper, “The conception of wholes and parts in early infantile autism.”

Current Knowledge

The notion that people with ASD have a more detail-focused processing style than NTs has become popular not only with researchers but also with teachers, parents, and those with ASD. A recent poster by the National Autistic Society in the UK showed a close-up of an eye, with the words, “*When a person with autism walks into a room, the first thing they see is: A pillow with a coffee stain shaped like Africa, a train ticket sticking out of a magazine, 25 floorboards, a remote control, a paperclip on the mantelpiece, a marble under the chair, a crack in the ceiling, 12 grapes in a bowl, a piece of gum, a book of stamps. . . so it’s not surprising they ignore you completely.*” The idea of weak coherence fits with descriptions by individuals with ASD of their own experience: for example, Gunilla Gerland (1997) writes, “*Every little bit of fact seemed to land in its own compartment in my head and refused to be linked*

with any other.” The emphasis on understanding strengths, as well as weaknesses, in ASD has been particularly welcomed and has led to “weak” coherence often being referred to instead as “detail-focused” processing.

Studies to date suggest that weak coherence is a cognitive *style*, not deficit, and may be best conceptualized as an information-processing bias towards local or featural information (Booth and Happé 2010). This bias can be overcome, just as NTs can overcome their preference for meaning to memorize “meaningless” information such as telephone numbers or bank codes. So, for example, people with ASC *can* read text for meaning, but unless asked to do so explicitly, their default approach may be to read a story as if it were just a list of words (e.g. not using context to disambiguate homographs; Happé 1997). A natural eye for detail appears to play a part in the unusually high rate of savant skills in ASC (Happé and Vital 2009), facilitating, for example, absolute pitch as a basis for further musical skills. Even the child with ASC who is terribly distressed by a familiar ornament being moved a fraction of an inch is demonstrating a special skill and attention to detail that few NTs possess.

Whether the good eye and memory for detail in ASD comes at the expense of processing the meaning and bigger picture is a topic of much debate. Several alternative accounts of superior local processing in ASC (including Baron-Cohen’s “hyper-systemizing” and Mottron’s “enhanced perceptual functioning” theories) propose that global processing is intact in ASD (Mottron et al. 2006). Recently, Happé and Booth (2008) have suggested that weak coherence may be the result of two somewhat independent aspects, superior featural processing and poor global processing, with different subgroups within ASD showing only the former, only the latter, or both, of these.

Studies to date suggest that detail-focused processing bias is not secondary to so-called executive dysfunction: impulsivity and poor planning in ADHD, for example, do not result in the characteristic assets or deficits associated with weak coherence in ASD (Booth et al. 2003). The relationship between weak coherence and “Theory of

Mind” deficits is less clear, although a degree of independence seems likely as, for example, some fathers of children with ASD show excellent eye for detail without accompanying social difficulties (Happé et al. 2001). Weak coherence may also be relevant to other special groups; for example, recent work suggests superior eye for detail in some women with eating disorders (Lopez et al. 2008).

To date, the brain basis of weak coherence is unclear, although the theory chimes well with suggestions of reduced functional connectivity, stronger local than long-range neural connections, and reduced top-down modulation (e.g., Belmonte et al. 2004). The working hypothesis is that weak coherence is among the features of the “broader autism phenotype,” inherited in many cases of ASC. Importantly, ongoing work suggests an overlap between genetic influences on ASC-like eye for detail and genetic influences on talent in maths, music, art, or memory (Happé and Vital 2009).

Future Directions

At least three areas are likely to be important in future research on weak central coherence. First, functional brain imaging studies are needed to better understand the neural basis of this cognitive style, in ASD and in the general population. Second, research on the link between detail-focused style and talent might inform educational approaches to encourage talent development in individuals with ASD and those without. Finally, an important aim for future research is to develop educational interventions based on the weak coherence hypothesis, helping children with ASD learn to see the bigger picture where needed while also capitalizing on their natural strength in noticing and remembering details.

Wechsler Memory Scale (All Versions)

Hillary Hurst

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Description

The Wechsler Memory Scale (WMS) is a neurocognitive assessment tool designed for individuals aged 16–90 years old. Since memory functioning cannot be measured directly, it must be assessed via other cognitive skills, like verbal ability (Holdnack et al. 2011). The WMS measures different facets of human memory, including visual memory, auditory memory, and working memory.

Historical Background

Introduced in 1945, the original WMS has undergone several major revisions, including Russell's WMS-Revised (1975, 1988), the WMS-R (1987), WMS-III (1997), and the WMS-III Abbreviated (2002). Each of these revisions built upon the previous version and reflected evolving theories about memory. Published in 2009, the WMS-IV is the most current version and is designed to complement the Wechsler Adult Intelligence Scale (WAIS-IV); this is very helpful in cases where the goal of testing is to compare an individual's memory functions with his/her other cognitive abilities. The validation sample of the WMS-IV consisted of 100 participants per age band, for a total sample of 1400; the co-validation WAIS-IV/WMS-IV sample consisted of 900 individuals (Holdnack et al. 2011). These samples were stratified nationally by sex, education level, ethnicity, and region. The WMS-IV is innovative in that it

also includes an Older Adult Battery, a modified version of the WMS-IV specifically for examinees between the ages of 65 and 90 years old. The goals put forth by the publisher in designing the WMS-IV include: improving clinical sensitivity, decreasing testing time for older adults, improving forensic utility, reducing confounding factors, eliminating repetition or overlap with the WAIS, improving assessment of working memory, and improving ease of scoring and administration.

Psychometric Data

The WMS-IV consists of seven subtests, four of which are new to this edition and three that are adapted from the WMS-III. The subtests have generally high internal consistencies, ranging from 0.97 to 0.74, and are even higher among some clinical populations, such as individuals with Alzheimer's disease. The subtests are generally presented in the following order:

General Cognitive Screener

The Brief Cognitive Status Exam (BCSE) is a screener for significant cognitive impairment, which if present, could significantly impact test performance. The BCSE contains items that assess orientation to time, incidental recall, mental control, planning/visual perceptual processing, inhibitory control, and verbal productivity. Performance on this subtest is classified as Average, Low, Moderately Low, and Very Low. The BCSE was introduced in the WMS-IV, replacing the former Mental Control, and Information and Orientation subtests. Of the seven subtests of the WMS-IV, this is the only one that is considered to be optional.

Logical Memory

In Logical Memory I, the examinee is presented with information orally, in a story format, and is immediately asked to recall as many specific details about the story as possible. The general WMS-IV contains two stories; the Older Adult Battery contains only one story that is presented twice. In Logical Memory II, the examinee is asked to recall specific details about the

information following a 20–30 min delay, and also to answer some yes or no questions about it. Thus, Part I measures auditory immediate memory whereas Part II measures auditory delayed memory and auditory delayed recognition. Logical Memory was included in previous versions of the WMS and was modified slightly for the WMS-IV. These changes include eliminating a repetition of a story in the general battery, making small factual changes within a story to address clinician feedback, and including a new story in the Older Adult Battery. Logical Memory I has an internal reliability of 0.82 (0.86 for the Older Adult Battery) and Logical Memory II has an internal reliability of 0.85 (0.87 for the Older Adult Battery). The test-retest reliability of Logical Memory I is 0.72 (0.77 for the Older Adult Battery) and of Logical Memory II is 0.67 (0.71 for the Older Adult Battery).

Verbal Paired Associates

In Verbal Paired Associates I, the examinee is presented with a series of word pairs and is immediately asked to recall them, following a prompt including the first word of the pair. In Verbal Paired Associates II, the examinee is asked to recall these word pairs following a 20–30 min delay (again, following a prompt including the first word of the pair) and also to identify which pairs were presented earlier, from a list of words pairs. Part I of Verbal Paired Associates measures immediate learning of verbal associations and Part II measures delayed cued recall for these verbal associations, as well as long-term auditory recall. The California Verbal Learning Test – Second Edition (CVLT-II) is another measure that requires verbal list-learning and measures auditory verbal memory, and it is similar enough to the Verbal Paired Associates subtest that it is identified as an acceptable alternative to the WMS-IV. The CVLT-II can be used as a substitute for Verbal Paired Associates if an examinee has particular difficulty with words pairs that are not semantically related. Verbal Paired Associates was included in previous versions of the WMS and was modified significantly for the WMS-IV. These changes include the addition of easier items to increase the range of scores, and the

addition of Word Recall, an optional free recall condition that requires the examinee to recall, without cues, as many of the original word pairs as possible. Verbal Paired Associates I has an internal reliability of 0.94 (0.93 for the Older Adult Battery) and Verbal Paired Associates II has an internal reliability of 0.85 (0.74 for the Older Adult Battery). The test-retest reliability of Verbal Paired Associates I is 0.76 (also 0.76 for the Older Adult Battery) and of Verbal Paired Associates II is 0.76 (0.77 for the Older Adult Battery).

Designs

In Designs I, the examinee is presented with a series of grids that contain black and white geometric designs for 10 s. Next, the examinee is presented with grids containing new designs, and is asked to identify the locations of the previous designs within them. In Designs II, the examinee is presented with a series of grids and is asked to identify the locations of the original designs following a 20–30 min delay; additionally, the examinee is asked, in a multiple-choice format, to indicate which grids have the correct original designs and locations following a delay. This subtest differentiates one's capacity for visual details and spatial recall and was introduced in the WMS-IV, replacing the former Family Pictures and Faces subtests. The internal reliability of both Designs I and Designs II is 0.85; the test-retest reliability of Designs I is 0.73 of Designs II is 0.72. Designs is excluded from the Older Adult Battery.

Visual Reproduction

In Visual Reproduction I, the examinee is shown a series of five designs for 10 s each. Then, the picture is removed and the examinee is asked immediately to draw it from memory. In Visual Reproduction II, the examinee must draw the same target designs following a 20–30 min delay, without any cues. Also, the examinee must identify the target designs in a multiple-choice format following a delay. An optional condition requires the examinee to copy the original designs while the target design is displayed; this serves as a control for the examinee's visuospatial

skills. Overall, the Visual Reproduction subtest measures short- and long-term visual memory and long-term visual recall. It was included in previous versions of the WMS and was modified significantly for the WMS-IV. These changes include quicker and easier scoring rules for examiners, a return to a 7-item visual discrimination format, and the copy condition, described above. Visual Reproduction I has an internal reliability of 0.93 (also 0.93 for the Older Adult Battery) and Visual Reproduction II has an internal reliability of 0.97 (0.96 for the Older Adult Battery). The test-retest reliability of Visual Reproduction I is 0.62 (0.79 for the Older Adult Battery) and of Visual Reproduction II is 0.59 (0.64 for the Older Adult Battery).

Spatial Addition

In Spatial Addition, the examinee is shown a grid with a pattern of blue and/or red dots, which is immediately followed with a second grid with blue and/or red dots. In these trials, the blue dots are the target and the red dots are the distractor. The examinee then is given another grid, along with white cards and cards with blue dots, and is asked to perform addition, based on rules presented through the previous two grids, to show where the dots should appear on the new grid. This subtest measures spatial working memory and requires the storage and manipulation of visual information, as well as the ability to ignore competing stimuli. Spatial Addition was introduced in the WMS-IV, replacing the former Spatial Span subtest. The internal reliability of Spatial Addition is 0.91; its test-retest reliability is 0.74. Spatial Addition is excluded from the Older Adult Battery.

Symbol Span

In Symbol Span, the examinee is presented with novel symbols in a specific order and is then asked to identify them, in that order, on a page with many different symbols. This subtest measures visual-sequencing working memory, or the capacity to retain a mental image of a symbol and its relative spatial position. Symbol Span was introduced in the WMS-IV as a visual complement to the WAIS-IV subtest Digit Span. The internal

reliability of Symbol Span is 0.88 (0.84 for the Older Adult Battery) and its test-retest reliability is 0.72 (0.69 for the Older Adult Battery).

Older Adult Battery

The Older Adult Battery is a modified version of the WMS-IV that is specifically for examinees between the ages of 65 and 90. It does not contain the Designs and Spatial Addition subtests and requires only half the time as the complete WMS-IV (45 min, as opposed to 75–90 min). Because the Spatial Addition subtest is not administered, a Working Memory Index Score is not calculated for the Older Adult Battery.

Calculation of Index Scores

Subtest raw scores are converted into scaled scores that have a mean of 10 and a standard deviation of 3. Subtests contribute to five indices: Immediate Memory Index (Logical Memory I, Designs I, Visual Reproduction I, and Verbal Paired Associates I), Delayed Memory Index (Logical Memory II, Designs II, Visual Reproduction II, and Verbal Paired Associates II), Visual Working Memory Index (Spatial Addition and Symbol Span), Auditory Memory Index (Logical Memory I and II, and Verbal Paired Associates I and II), and Visual Memory Index (Designs I and II, and Visual Reproduction I and II). Standard scores are derived for each of these five indices, with a mean of 100 and a standard deviation of 15.

Index scores are the basis for interpreting WMS-IV performance as they are more psychometrically sound than individual subtest scores. The internal reliabilities of the indices are very high, ranging from 0.93 (Visual Working Memory Index) to 0.98 (Visual Memory Index) for the 16–90 battery, and from 0.92 (Delayed Memory Index) to 0.97 (Visual Memory Index) for the Older Adult Battery. The test-retest reliability of the indices is good, ranging from 0.79 (Delayed Memory Index) to 0.82 (Visual Working Memory Index) for the 16–90 battery, and from 0.79 (Visual Memory Index) to 0.84 (Immediate Memory Index) for the Older Adult Battery. The Immediate Memory Index indicates one's capacity to encode and retrieve both verbal and visual information very shortly after its presentation; the

Delayed Memory Index indicates one's capacity to perform the same functions but after a longer period of time. The Visual Working Memory Index captures one's ability to work with information that is presented visually, including retaining, organizing, and manipulating it. The Auditory Memory Index indicates one's capacity for encoding and retrieving information that is presented verbally, both immediately and following a delay, and the Visual Memory Index measures the same abilities, except for information that is visual in nature. Index-level contrast scaled scores are calculated to determine whether differences between index scores for a given examinee are statistically significant or within the expected ranges of variation.

Clinical Uses

There are a number of factors that can negatively impact one's performance on the WMS subtests, including disabilities (visual, auditory, physical, speech, and language), lack of familiarity with the testing format, and limited English proficiency. The balance of verbal and nonverbal tests helps to account for these factors. Also, conditions such as Alzheimer's disease, schizophrenia, traumatic brain injury, and intellectual disability have been associated with lower scores on the WMS. There are also factors that can falsely inflate one's performance. Memory and learning measures are subject to significant practice effects, in which one's performance increases with increased exposure to the testing materials. On the WMS-IV, these increases may approach one standard deviation. Therefore, retesting within a short time period (for example, 1–3 months) can lead to invalid results.

As the WMS-IV is a relatively new instrument, little research has documented how individuals with ASD perform on it. Twenty-two individuals with autism were included in the official validation sample of the WMS-IV and preliminary studies suggested that they, along with adults with schizophrenia and traumatic brain injury, performed in the Low Average range on Designs I and II. Additionally, participants with autism

performed significantly worse on the Spatial Addition and Symbol Span subtests than those without autism. It is important to keep in mind that these results are based on a very small sample and that additional research is needed to understand how individuals with ASD may perform on the new WMS-IV subtests.

Previous research compared the performance of individuals with ASD and that of individuals without ASD on the WMS-III. While people with and without ASD performed comparably on memory for words pairs, stories, and a verbal working memory task, individuals with ASD performed worse on immediate and delayed recall of faces and family scenes – which are not included in the WMS-IV – and on a test of spatial working memory (Williams et al. 2005). Other research has examined memory function in adolescents and young adults with ASD with measures other than the WMS. For example, Minshew and Goldstein (2001) found that individuals with ASD performed worse than those without ASD on some tasks comparable to those included in the WMS, including a list-learning task, and an immediate and delayed story recall, and that these results may have been due to weaknesses in higher-level mental organization and a failure to attend to contextual or semantic clues.

Description

The Wechsler Preschool and Primary Scale of Intelligence – Third Edition (WPPSI-III) is an individually administered clinical instrument for assessing the intelligence of children aged 2 years 6 months through 7 years 3 months (2:6–7:3). Its age range is divided into two age bands (2:6–3:11 and 4:0–7:3) each with its own battery of subtests. The WPPSI-III provides composite scores that represent intellectual functioning in specified cognitive domains such as Verbal IQ and Performance IQ. The verbal areas are considered auditory/vocal tasks (auditory input and vocal output), and the performance areas are considered visual/vocal (visual input and vocal output) and visual/motor tasks (visual input and motoric output). The WPPSI-III also provides a composite score that represents a child's general intellectual ability (Full Scale IQ). All standard scores have a mean of 100 and a standard deviation of 15. All subtests yield a scaled score with a mean of 10 and a standard deviation of 3. Administration time is between 60 and 75 min in an individual format. Testing materials can be obtained through the publishing company (Pearson) to a qualified examiner. Computerized scoring and interpretation is available.

Structure

There are three types of subtests: core, supplemental, and optional.

Core. Completion of the core subtests yields Full Scale IQ (FSIQ), Verbal IQ (VIQ), and Performance IQ (PIQ). Composite scores can be judged in relation to norms and can guide clinical judgment.

Ages 2:6–3:11

- Receptive Vocabulary
- Information
- Block Design
- Object Assembly

Full Scale IQ = Verbal Domains, Performance Domains

Verbal = Receptive Vocabulary and Information

Performance = Block Design and Object Assembly

Ages 4:0–7:3

- Information
- Vocabulary
- Word Reasoning
- Block Design
- Matrix Reasoning
- Picture Concepts
- Coding

Full Scale IQ = Verbal Domains, Performance Domains, and Coding Subtest

Verbal = Information, Vocabulary, Word Reasoning

Performance = Block Design, Matrix Reasoning, Picture Concepts

Coding Subtest

Supplemental. These subtests can be used to substitute for core subtests and derive additional composite scores. Processing Speed Quotient (PSQ) for ages 4:0–7:3. General Language Composite (GLC) for ages 2:6–3:11.

Ages 2:6–3:11

- Picture Naming

General Language Composite (GLC) = Picture Naming and Receptive Vocabulary (from Core subtests)

Ages 4:0–7:3

- Symbol Search
- Comprehension
- Picture Completion
- Similarities
- Object Assembly

Processing Speed Quotient (PSQ) = Coding (from Core subtests) and Symbol Search

Optional. These subtests are not used to substitute for any core subtest.

Ages 4:0–7:3

- Receptive Vocabulary
- Picture Naming

General Language Composite (GLC) = Receptive Vocabulary and Picture Naming

Some subtests can be core, supplemental, or optional depending on the age of the child (e.g., Receptive Vocabulary subtest is a core verbal subtest for ages 2:6–3:11 but is optional for ages 4:0–7:3).

Supplemental Verbal subtests are Comprehension and Similarities. Either of these subtests may be substituted for one core Verbal subtests. Supplemental Performance Subtests are Picture Completion and Object Assembly. Either of these subtests may be substituted for one core Performance subtest. Symbol Search is a supplemental Processing Speed subtest and can be used to either substitute for the core Processing Speed subtest (Coding) or added to the Coding to then derive the Processing Speed Quotient (PSQ).

Optional subtests may be used to provide measure of expressive and receptive vocabulary ability in older children with language delays but may not be substituted for core Verbal subtests. Further, Receptive Vocabulary and Picture Naming allow the practitioner to calculate the General Language Composite.

Description of Subtests

Information. (2:6–7:3 Core, Verbal, 34 items including 6 picture and 28 verbal). This subtest is designed to assess a child's ability to acquire, retain, and retrieve general factual knowledge. This knowledge is referred to as a general fund of knowledge that includes crystallized intelligence, long-term memory, and the ability to retain and retrieve knowledge from school and the environment. General information is acquired from experience and education, remote verbal memory, understanding, and associative thinking. Other skills that could contribute include auditory perception and comprehension and verbal expressive ability. The picture ($n = 6$) items do not require a verbal response and were designed for the youngest children. They require the child to respond to a question by choosing a picture from a field of four commonplace objects. Verbal items require a brief verbal response from each child.

Vocabulary. (4:0–7:3 Core, Verbal, 25 items including 5 picture 20 verbal). This subtest is designed to assess a child's understanding of spoken words, learning ability, general range of ideas,

verbal information acquired from experience and education, and kind and quality of expressive language. Focus is on child's word knowledge and verbal concept formation that includes a child's fund of knowledge, learning ability, long-term memory, and degree of language development. Other abilities that could contribute include auditory perception and comprehension, verbal conceptualization, abstract thinking, and verbal expression. For the picture items, the child names the pictures that are displayed in a stimulus book (one per page). For the verbal items, the child gives definitions for words that the examiner reads aloud.

Word Reasoning. (4:0–7:3 Core, Verbal, 28 items). This subtest is designed to measure reasoning with verbal material and includes successive clues for the child to identify the underlying concept. The clues are in a series and are increasingly specific. This task assesses verbal comprehension, analogic and general reasoning ability, ability to integrate and synthesize different types of information, verbal abstraction, and domain knowledge, and the ability to generate alternative concepts.

Comprehension. (4:0–7:3 Supplemental, Verbal, 20 items). This subtest measures social judgment and maturity, common sense, verbal reasoning based upon experience, practical intelligence/knowledge of conventional standards of behavior, and conceptualization. This subtest measures the ability to evaluate and utilize past experience, verbal comprehension and expression, and the ability to demonstrate practical information. All items require the child to answer questions based on the understanding of general principals and social situations.

Similarities. (4:0–7:3 Supplemental, Verbal, 24 items). This subtest measures abstract and concrete verbal reasoning, concept formation, logical thought processes, associative thinking, and remote memory. It involves auditory comprehension, memory, the ability to distinguish between nonessential and essential features, and verbal expression. The subtest questions involve sentence completion with a response that reflects a shared characteristic. The child is read an incomplete sentence that contains two concepts sharing a common characteristic.

Receptive Vocabulary. (2:6–3:11 Core, Verbal/4:0–7:3 Optional, Verbal, 38 items). This subtest measures a child's understanding of spoken words, understanding of verbal directives, auditory and visual discrimination, auditory memory and processing, learning ability, general range of ideas, ability to integrate visual perception and auditory input, verbal information acquired from experience and education, and kind and quality of expressive language. Responses may be influenced by phonological memory and working memory. This subtest is relatively unaffected by emotional disturbance but is highly susceptible to cultural background and level of education. It is the best single measure of intelligence in the entire battery. The child looks at a group of four pictures and points to the one the examiner names aloud.

Picture Naming. (2:6–3:11 Supplemental, Verbal/4:0–7:3 Optional Verbal, 30 items). This subtest measures expressive language ability, word retrieval from long-term memory, and association of visual stimuli with language. The child names a picture that is displayed in the stimulus book.

Block Design. (2:6–7:3 Core, Performance, 20 items). This subtest measures the ability to perceive, analyze, synthesize, and reproduce abstract visual stimuli. It involves nonverbal concept formation, visual perception and organization, simultaneous processing, visual-motor coordination, learning, spatial relationships, and the ability to separate figure and ground in visual stimuli as well as the ability to plan and organize. For younger children, skills involve visual observation and matching ability as well as the ability to integrate visual and motor processes. Children are required to recreate a design created in the child's view within a specified time limit. This subtest is divided into two parts (A and B). Part A (items 1–10) involves one-color blocks and rotation is not penalized. Items 1–6 have two trials. Thus, it was designed for the youngest children. Part B (items 11–20) involves viewing and constructing a model or picture in a stimulus book, the use of one- or two-color blocks, and rotations of 30° or more are penalized.

Matrix Reasoning. (4:0–7:3 Core, Performance, 29 items). This highly reliable estimate of general intellectual ability measures fluid

reasoning. Matrix reasoning tasks are relatively culture-fair and language-free requiring no hand manipulation. This reliable measure of visual information processing and abstract reasoning skills utilizes four types of matrices. The first is continuous and discrete pattern completion, classification, analogic reasoning, and serial reasoning. The child looks at an incomplete matrix/grid and selects the missing piece to properly complete the matrix from 4 to 5 response options.

Picture Concepts. (4:0–7:3 Core, Performance, 28 items). This subtest measures fluid reasoning, perceptual organization, and abstract categorical reasoning without a verbal response. Items are developmentally sequenced to reflect increasing demands on abstract reasoning abilities. Easier questions are more concrete (e.g., color, shape, appearance), and the more difficult items require responses based upon more abstract representations (e.g., functions of an object). From each of two or three rows of object, the child selects objects that form a group with a common characteristic based upon an underlying concept.

Picture Completion. (4:0–7:3 Supplemental, Performance, 32 items). This subtest is designed to measure visual alertness to surroundings, remote visual memory, visual perception and organization, concentration, visual attention to detail, and ability to isolate essential from nonessential detail. All items require the child to view a picture and point to or name the important part missing from the picture.

Object Assembly. (2:6–3:11 Core, Performance/4:0–7:3 Supplemental, Performance, 14 items). This subtest measures immediate perception of a total configuration, integration and synthesis of part-whole relationships, nonverbal reasoning, and trial and error learning, spatial ability, visual-motor-spatial coordination, cognitive flexibility, and persistence. The child is presented with a standardized configuration of puzzle pieces and allowed 90 s to fit the pieces together to form a meaningful whole.

Symbol Search. (7:0–7:3 Supplemental, Processing Speed, 120 s). This subtest assesses visual discrimination, short-term visual memory, visual motor coordination, cognitive flexibility, and concentration. It also may involve auditory

comprehension, perceptual organization, and planning and learning ability. The child scans a search group and indicates whether a target symbol appears in the search group by marking the appropriate symbol with a pencil.

Coding. (4:0–7:3 Core, Processing Speed, 120 s). This subtest measures ability to associate meaning with symbols, visual-motor coordination and dexterity (pencil manipulation), flexibility and speed in learning tasks, short-term memory, visual perception, visual scanning ability, cognitive flexibility, attention, and motivation. It also may involve visual and sequential processing. The child copies symbols that are paired with simple geometric shapes. Using a key, the child draws each symbol in its corresponding shape.

Historical Background

In the early twentieth century, prevalent theories of intelligence emphasized a single, underlying construct of intelligence as largely responsible for an individual's performance on all mental tasks. The definition of intelligence, or cognitive ability, evolved as professionals developed ways to measure it. Indeed, experts have agreed that there are overwhelmingly three elements that make up the most important aspects of cognitive ability. They are the ability to deal with abstractions (ideas, symbols, relationships, concepts, and principles), the ability to solve problems (to deal with new situations, not simply to make well-practiced responses to familiar situations), and the ability to learn (the ability to grasp and use abstractions of the kind involving words and other symbols). Psychologists such as Spearman (1904) and Cattell (1941, 1957) introduced the theory that intelligence was comprised of two general factors. The first is fluid intelligence or generalized intelligence which is defined as the ability to perceive relationships independent of previous specific practice or instruction regarding these relationships. It is the ability to manipulate and think abstractly and solve problems. It is considered independent of learning. The second is crystallized intelligence which involves learning from contexts and materials previously learned (e.g.,

reading comprehension, vocabulary exams). This intelligence is based upon facts and rooted in experiences. It grows as people age and accumulate new knowledge and understanding.

Tests to measure intelligence, or cognitive ability, were developed in the latter half of the nineteenth century and reflected the social milieu in which they occurred. The majority of tests were developed for school-aged children, while the assessment of preschool-age children came later and is a relative newcomer in the history of testing.

In 1905, Binet and Simon developed tasks to measure the intelligence of children within the Paris public schools in response to the French government commission aimed at developing methods to identify children who would not benefit from regular education. These tasks were primarily language oriented, emphasizing judgment, memory, comprehension, and reasoning. After two revisions (1908, 1911), the scale extended from age 3 to 13 and included five adult tests. Others revised the assessment again in 1912, 1914, and 1916 and extended the assessment downward to 2 months of age (although these early tests were methodologically lacking) and to the United States (Terman and his colleagues). The primary focus of intelligence testing continued to be aimed at identifying intellectual deficiencies.

Around the time the US entered into World War I, the focus of intelligence testing began to change. There was a need to use an intelligence measure to screen recruits. The Army Alpha was created and included a large verbal component, and thus the Army Beta was subsequently developed to address the recruits with limited literacy skills to provide a nonverbal measure of intelligence.

In 1925, the understanding of “developmental schedules” began to evolve as Gesell identified four areas of development (motor, language, adaptive, and personal social) in 10 age levels (birth, 4, 6, 9, 12, 18, 24, 36, 48, and 60 months). This work helped guide the understanding of early developmental profiles which then were subsequently used in the development of tests for infants and preschoolers. Key infant and

preschool assessments of development and cognition were published in the first half of the twentieth century (Merrill-Palmer Scale of Mental Tests – Stutsman 1931; Minnesota Preschool Scale – Goodenough 1926; the Bayley California First-Year Mental Scale – Bayley 1933; and the Iowa Test for Young Children – Fillmore 1936); however, these assessments focused more on mental and physical growth than on intelligence. Tests for infant preschool *intelligence* were developed in the 1940s (Cattell Infant Intelligence Scale – Cattell 1940; Northwest Infant Intelligence Scale – Gilliland 1949; the Leiter International Performance Scale – Leiter 1948; the Full-Range Picture Vocabulary Test – Ammons and Ammons 1948; and the most widely used Stanford-Binet – 1949). These assessments were primarily designed as psychometric tools.

David Wechsler had strong clinical skills and statistical training with his extensive experience in testing gained initially from the World War I examinations and screenings in which he participated. His developed assessments were first introduced in the mid-1930s and weighted verbal and nonverbal abilities equally which was innovative at that time. As the social culture in the 1950s began to expand to the concept of identifying and diagnosing the nature of learning disabilities in children, the intelligence tests that focused on measuring more discrete aspects of an individual's cognitive functioning became very valuable. Wechsler's goals were to create batteries that yielded dynamic clinical information from his chosen set of tasks.

The original assessment was the Wechsler-Bellevue that was based upon the premise that intelligence is a global entity, characterizing the individual's behavior as a whole, and it is also specific because it is composed of elements or abilities that are distinct from each other. Thus, he developed subtests that highlighted the cognitive aspects of intelligence: abstract reasoning, perceptual organization, verbal comprehension, quantitative reasoning, memory, and processing speed. Wechsler's concept of intelligence was not a two-factor structure of intelligence. Instead, the two areas (verbal and performance) are different measures of intelligence, not measures of

different kinds of intelligence. He concluded that the Verbal and Performance subtests were only one of several ways in which the tests could be grouped.

In the 1960s, the US federal government became involved in education (e.g., Head Start), and this involvement warranted the assessment of preschool children. There was a need for effective program evaluation at the preschool level (both concurrent and predictive). In 1967, the Wechsler Preschool and Primary Scale of Intelligence (WPPSI) was developed to meet that need. It was a downward extension of the Wechsler Intelligence Scale for Children, and it had simpler items and an appropriately aged standardization sample; however, the age range was 4 years to 6 ½ years which did not address the need of early start programs. In 1975, again due to federal involvement in education through Public Law 94-142, the Education for All Handicapped Children Act, there was a need to evaluate and diagnose children's levels of functioning. These laws directly affected the continued development of standardized testing, and the WPPSI was revised in 1989 (WPPSI-R) and expanded the age range to include 3 years through 7 years 3 months as well as the addition of both easier and more difficult items to the original subtests. Age determined starting points were introduced to reduce the overall administration time. In 2002, a third revision (WPPSI-III) was published to first update the theoretical foundations by additional composite scores, enhancing the measure of fluid reasoning and incorporating measures of processing speed. Second, the assessment was revised to increase the developmental appropriateness by dividing the assessment into two age bands: 2 years 6 months to 3 years 11 months and 4 years to 7 years 3 months. Further, the instructions were simplified, the test materials were updated, time constraints and expressive language confounds were reduced, and items/queries/prompts were added as options. Third, the assessment was designed to enhance the clinical utility by increasing the number of special group studies (gifted, developmental delay, mental retardation, etc.), extending the age range, and updating statistical linkage to measures of achievement. Fourth,

psychometric properties were improved by updating the norms, by adding additional evidence of reliability and validity, by extending the floor and ceiling, and by reexamining bias. Finally, user-friendliness was increased by reducing the testing time, reorganizing the manual and the record form, and simplifying administration procedures. The WPPSI-III addresses the developmental period that involves some of the most profound changes in children's cognitive abilities.

Psychometric Data

Development and Standardization Procedures

The WPPSI-III development was a 4-year iterative process where each phase of development leads to further refinements of the scale. The AERA 1999 Standards for Educational and Psychological Testing served as primary resources. Test development occurred in five general stages: conceptual development, pilot, national tryout, standardization, and final assembly and evaluation.

Conceptual Development. An advisory panel with nationally recognized experts in school psychology, clinical psychology, neuropsychology, and cognitive development was assembled to work with the team throughout the process. Early in the development, a group of 106 professionals participated in a focus group to refine goals and assist in the formulation of the initial scales. Further, two telephone surveys were conducted with users of the WPPSI-R and professionals in childhood assessment. Finally, semi-structured surveys of other experts and examiners were conducted at all stages of test development to rate the research versions of the scale on such qualities as developmental appropriateness, user-friendliness, and clinical utility. In all, results were summarized and discussed, and at all stages of development, modifications to the working blueprint and research versions of the scale were integrated.

Pilot Stage. The goal of the pilot stage was to produce a version of the scale for use in the next stage (the national tryout stage). The focus was to

examine any content issues, relevance of items, adequacy of floors and ceilings, the clarity of instruction, identification of responses processes, administration, scoring, and item bias.

National Tryout Stage. The version used included 17 subtests, and data was obtained from a stratified sample of 424 children representatives of key demographic variables in the national population. Stratification occurred along age, sex, race, parent education level, and geographic region. Further, special group data were collected (e.g., groups of participants with mental retardation, intellectual giftedness, and language disorder as well as oversample of African American and Hispanic children) to provide additional understanding of the adequacy of the subtests and the clinical utility of the scale.

Standardization Sample. After collecting data from the national tryout stage, a standardization edition of the WPPSI-II was created. All preceding research questions were reexamined using similar research methods, but at this stage, the focus was on the derivation of norms and the provision of reliability, validity, and clinical utility. The WPPSI-III was standardized on a sample of 1700 children aged 2:6–7:3 who were chosen to match closely with the 2000 US census data on the variables of gender, geographic region (Northeast, South, Midwest, and West), parent education (0–8 years, 9–11 years, 12 years which was high school degree or equivalent, 13–15 years which was some college or associate's degree, and 16 or more), and ethnicity (Whites, African Americans, Hispanics, Asians, and other). The sample was divided into nine age-groups of 200 each (2:6–2:11, 3:0–3:5, 3:6–3:11, 4:0–4:5, 4:6–4:11, 5:0–5:5, 5:6–5:11, 6:0–6:11) and 7:0–7:3 which included 100 participants. The group was evenly split in gender.

Trained recruiters and independent examiners identified the children meeting the specified inclusion criteria for the standardization sample. Both the child and parents were paid an incentive fee for participation. Subjects were excluded if they were tested on any intelligence measure in the previous 6 months, had uncorrected visual and/or hearing loss, were not English speaking, had an upper extremity disability that would affect

motor performance, were admitted to a hospital or psychiatric facility, were taking medications that might depress test performance, or had a previously diagnosed physical condition or illness that might depress test performance.

Final Assembly. The consistency of the item sets, instructions, and stimulus material was evaluated throughout the development process and retained, modified, or deleted. Further, a special study was conducted to examine the possible effects of a new testing order using a within-subjects design. Sixty children aged 4:0–7:3 were administered 14 subtests in the proposed order for the final scale and matched to 60 children from the standardization sample, and no significant differences were found. To establish a quality assurance procedure, qualified examiners were found, a computer program automatically checked the values entered by scorers, and scoring studies were conducted to determine the underlying response process.

Statistical Properties

Reliability. Reliability refers to the accuracy, consistency, and stability of test scores across situations. True scores are hypothetical and defined as what an examinee would score if the test were perfectly reliable. The difference between a true score and an examinee's obtained score is measurement error. A reliable test would thus have very small measurement error as it would be consistent within one administration and on different occasions.

Internal Consistency. The evidence for internal consistency was obtained using the normative sample and the split-half method which was used in the WPPSI-R and divides subtest items with an odd-even split to form two half-tests. The reliability coefficient of the subtest is the correlation between the total scores of the two half-tests corrected by the Spearman-Brown formula for the full subtest. Coding and Symbol Search are timed subtests, and thus test-retest stability coefficients were used as reliability estimates. For the overall standardization sample, the average reliability coefficients range from .84 to .95 which are excellent ($\leq .90$) to good. The average internal consistency coefficients for Verbal IQ = .95,

Performance IQ = .93, Processing Speed Quotient = .89, General Language Composite = .93, and Full Scale IQ = .96.

Test-Retest Stability. The test-retest stability for the WPPSI-III was obtained on a sample of 157 children (13–27 children from each of the nine age-groups). The WPPSI III was administered a second time to establish stability to a group of children at an interval of a mean of 26 days (range 14–50 days). The sample was stratified (39.5% female, 66.2% White, 12.1% African American, 17.2% Hispanic, and 4.5% other). Average test-retest coefficients for the following were: Verbal IQ = .91, Performance IQ = .86, Processing Speed Quotient = .86, General Language Composite = .91, and Full Scale IQ = .92. The largest practice effects (scores increasing from first testing to second testing) across age bands were 5–6 points for Performance IQ and Processing Speech Quotient, while the average for all ages across the other domains were just under three points.

Validity. There are three major types of validity: content (does the assessment adequately sample relevant aspects of the construct being measured), criterion-related (scores are related to specified external criteria), and construct (when the construct measured by the test was actually measured).

The WPPSI-III research team established validity by utilizing evidence from the test content, the response process, the internal structure, and the relationship to other variables. First, using intercorrelation studies, all intersubtest correlations on the WPPSI-III were statistically significant. For both age bands, the presence of moderate to high correlations supports the premise that a general intelligence factor is present. Second, factor analytic studies were used to evaluate the internal construct structure of the WPPSI-III. For both age bands, results were consistent with the predicted factor model proposed. In short, the WPPSI-III is a two-factor test, Verbal and Performance. For ages 4:0–7:3, a third factor includes Processing Speed. When only the core subtests were analyzed, the WPPSI-III subtests each loaded on its predicted factor, with the exception of Picture Concepts at ages 6:0–7:3. It loaded onto

a Verbal subtest rather than on its intended factor (Performance). Finally, the relationship to other measures by locating constructions within a nomological network of known variables was conducted. The WPPSI-III was compared to the WPPSI-R, WISC-III, Bayley Scales of Infant Development-II, and Differential Abilities Scale. The global scales of these instruments correlated strongly with the WPPSI-III (.80–.89). The WPPSI-III Verbal Scale correlated substantially higher with the verbal scales of the WPPSI-R, WISC-III, and DAS than with the nonverbal scales of these instruments. The WPPSI IV and Wechsler Individual Achievement Tests II were both administered to 208 children to examine the relationship between the cognitive measure and academic achievement. The WIAT-II composites were variably correlated with the domain IQ scores of the WPPSI-III ranging from .31 (Processing Speed Index and WIAT-II Reading) to .78 (Full Scale IQ and Total Achievement WIAT-II).

Clinical Uses

Special Subgroups

Because the WPPSI-III is often used as part of a diagnostic assessment, its clinical utility and specificity was examined through a number of special group studies conducted concurrently with the scale's standardization. These samples were not randomly selected; instead, they were from a variety of educational and clinical settings. The sample sizes were small, and only group performance is reported. The following describes the special interest groups and their performance in the WPPSI-III:

- Intellectually gifted – this group obtained significantly higher Verbal, Performance, and Full Scale IQ than children in the normal population.
- Children with mild or moderate mental retardation. For the mild severity subgroup, composite score for the group for Full Scale IQ was 62.1. For the moderate severity subgroup, average Full Scale IQ for the group was 53.1.

- Children with developmental delays. Children in this group performed significantly worse than a matched control group with average Full Scale IQ score at 81.8.
- Children with developmental risk factors. On all domains, IQ ranged from 85.7 to 88.6 with the exception of Processing Speed where the average IQ for the group was 90.1.
- Children with autistic disorder. Consistent with research, the Performance IQ (mean 88.2) was significantly higher than the Verbal IQ (mean 70.6).
- Children with expressive language disorder. Both groups' mean composite score differences were greatest for Verbal IQ (mean 90.6) and Full Scale IQ (mean 90.1).
- Children with mixed receptive-expressive language disorder. Average Verbal IQ was 83.1, Performance IQ was 85.2, Processing Speed IQ was 82.7, Full Scale IQ was 81.9, and General Language Composite was 86.7 representing significantly lower mean scores than a matched control group.
- Children with Limited English Proficiency. No differences were found for Processing Speed and Performance IQ, but Verbal IQ averaged 80.2 and General Language Composite averaged 79.2.
- Children with attention-deficit hyperactivity disorder. In the research and clinical literature, traditional IQ scores have not been found to be useful in discriminating children and adults with ADHD. Children with the disorder typically achieve scores near the normative range. In this subsample, all scores (subtests and domain scores) were between 93.8 (Verbal IQ) and 97.4 (Performance IQ).
- Children with motor impairment. As expected, children with motor impairments scored significantly lower than the normative population on the Performance IQ (average 87.7) and marginally significantly lower on the Processing Speed IQ (average 89.9).

Results from the special group studies indicate that the WPPSI-III is valid and clinically useful (with the exception of the ADHD category, but this is not specific to the WPPSI-III but general to all intelligence tests).

Interpretation

- WPPSI-III scores should never be interpreted in isolation.
- Standard scores enable practitioners to compare scores within the WPPSI-III and between the WPPSI-III and other related measures.
- Age-corrected standard scores also allow for a comparison of children's cognitive functioning across other children of similar age.
- Other information (percentile ranks, descriptive classification, test-age equivalents) can also be used to benefit interpretation.

Profile analyses can be identified from both intraindividual and interindividual perspectives by comparing the child's score patterns across subtests or to the appropriate normative reference group. This can aid in identifying meaningful patterns of strengths and weaknesses.

Wechsler Test of Adult Reading

Alice S. Carter

Department of Psychology, University of Massachusetts Boston, Boston, MA, USA

Description

The *Wechsler Test of Adult Reading* (WTAR; Pearson 2001) was developed for estimating pre-

morbid (pre-injury) intellectual functioning and pre-injury IQ and memory abilities. The WTAR takes less than 10 min to administer and is appropriate for individuals between the ages of 16–89 years of age. It is composed of 50 words that have atypical grapheme to phoneme translations. A grapheme is a letter or set of letters that correspond to a sound, or phoneme, such as the *f* in the word fan, the *ph* in the word phone, or the *gh* in the word tough. The reason for relying on words that have unusual or irregular pronunciations is to test prior word knowledge by minimizing the individual's ability to apply standard pronunciation rules. Thus, the test attempts to rely on the individual's prior, or pre-injury, learning or knowledge of the word list that is presented. The rationale for this approach is that reading recognition is relatively stable, even when there is evidence of cognitive decline due to aging, illness, or brain injury.

The WTAR record form includes the WTAR stimulus words with correct pronunciations and item scoring with an area for recording demographic data, the individual's raw score, standard score, percentile rank, and a space for predicting pre-morbid IQ and memory functioning from the current WTAR performance.

An advantage of the WTAR is that it was co-normed with the United States (US) and United Kingdom (UK) versions of the *Wechsler Adult Intelligence Scale*®-Third Edition (WAIS®-III) and *Wechsler Memory Scale*®-Third Edition (WMS®-III). Estimating pre-morbid or pre-injury level of intellectual functioning may be useful in treatment planning. This co-norming allowed for the development of equations for predicting both the WAIS-III and WMS index scores from the WTAR. A large representative norming sample that was matched to both the US and UK populations was employed to provide demographic data that improves accurate prediction of pre-morbid IQ in neurological cases. There is extensive between group validity for individuals with Alzheimer's disease, Huntington's disease, Parkinson's disease, Korsakoff's syndrome, and Traumatic Brain Injury. However, there is limited information about individuals with autism spectrum disorders.

A key part of the rationale of the WTAR is the assumption of a normal development of reading skills prior to injury or cognitive decline. Individuals with ASD tend to perform well (and consistent with their level of cognitive ability) on mechanical reading and spelling (Minschew et al. 1994). Indeed, decoding or basic word identification, which is the skill that is assessed on the WTAR, is generally an area of strength amid poor reading comprehension (e.g., O'Connor and Hermelin 1994; Patti and Lupinetti 1993). Therefore, the WTAR may overestimate pre-morbid functioning. Just as assessment of single-word comprehension may overestimate general (sentence and paragraph) reading level (Newman et al. 2007), the WTAR may overestimate prior cognitive capacities. Moreover, given that a majority of individuals with ASD are routinely assessed throughout childhood and adolescence to determine their need for academic accommodations, assessment of pre-morbid functioning may be best accomplished through a review or earlier testing reports.

Wechsler, David

Alan S. Kaufman

Yale University School of Medicine, New Haven, CT, USA

David Wechsler (Fig. 1) was born on January 12, 1896, the youngest of seven children, to Moses Wechsler, a merchant, and Leah (Pascal) Wechsler, a shopkeeper, in Lespedi, Romania. The family immigrated to the United States in 1902 when famine and poor economic conditions in Romania led to “worsening the scapegoating of Jews and resulting in severe applications of existing anti-Jewish decrees” (Wasserman 2012, pp. 30–31). He died at the age of 85 in New York City on May 2, 1981.

His experiences just before, during, and after America’s entry into the World War I paved the way for him to become the world’s leading expert in intelligence testing and clinical assessment. In 1917, working with testing pioneer Robert S. Woodworth at Columbia University, Wechsler earned his M.A. in experimental psychopathology

on retention in Korsakoff’s psychosis; that same year, he also worked under E. G. Boring, scoring army intelligence tests, as a civilian volunteer. After induction, while serving in the army’s psychology division in Fort Logan, Texas, Corporal Wechsler administered individual intelligence tests, including the Stanford-Binet, to recruits who could not be validly assessed by the army group tests (e.g., illiterates, suspected malingerers). In 1919, as an army student at the University of London, he worked closely with Karl Pearson (who developed the coefficient of correlation) and Charles Spearman (who promoted the theory of general intelligence or “g”). He then studied at the Sorbonne for 2 years, specializing in experimental and physiological psychology (Edwards 1994). By the time he earned his Ph.D. in 1925, under Woodworth at Columbia (on the measurement of emotional reactions via the galvanic skin response), his meteoric career was already on the rise. As Wasserman (2012) notes, “Columbia was one of the few major universities that provided graduate experimental psychology training with a willingness to address applied problems, termed *experimental abnormal psychology* by Woodworth” (p. 31) (and later called *clinical psychology*).

“In many ways, David Wechsler was an unexpected success – coming to the United States as a child amid a flood of Eastern European immigrants, losing both parents by the age of 10, compiling a relatively ordinary academic record in high school and college (while graduating early),”... “and not having become a naturalized citizen prior to the war. Even so, these risk factors may have been somewhat ameliorated by the following: (1) the guidance of his accomplished older brother, pioneering neurologist Israel S. Wechsler, who became his caretaker and role model; (2) the opportunity to provide military service as an army mental test examiner, which allowed him to thereby quickly learn about assessment and make key professional contacts; and (3) receiving his graduate education and professional psychology training at an opportune time and place in the development of what eventually would become clinical psychology.” (Wasserman 2012, p. 30)

In the mid-1920s, Wechsler was in the first wave of clinical psychologists, a breed of scientist-practitioners that represented a notable departure from the purely academic and experimental tradition of the American Psychological Association (APA). He was among the first to set up a private clinical practice and, in 1932, became chief psychologist at Bellevue Psychiatric Hospital, a post he held until 1967. Concurrently (1933–1967), he was a faculty member at New York University College of Medicine. Wechsler's test development techniques (combining verbal and nonverbal skills to produce a truly global measure of intelligence, a notion first sparked by scoring the group-administered Army Alpha and Army Beta, verbal and nonverbal tests, respectively); (Yoakum and Yerkes 1920) and his clinical approach to the assessment of intelligence are among the greatest innovations in applied psychology during the twentieth century. "Probably the work of no other psychologists, including Freud or Pavlov, has so *directly* impinged upon the lives of so many people" (Matarazzo 1981, p. 1542). French pioneer Alfred Binet developed the first intelligence test in 1905 (the Binet-Simon) and Stanford psychologist Lewis Terman translated and adapted Binet's work within the United States to produce the Stanford-Binet Intelligence Scale in 1916. However, it was American psychologist David Wechsler who dramatically, and permanently, changed the face of intelligence testing when he published the Wechsler-Bellevue (W-B), for ages 7–69 years, in 1939 (known in the literature as the W-B Form I because Form II was published in 1946).

Wechsler's intelligence (or "IQ") tests departed from Binet's and Terman's approach to measuring mental ability. Binet and Terman used mostly verbal tasks to measure intelligence, whereas Wechsler added a performance (nonverbal) scale to a verbal scale, with both contributing equally to a person's full-scale IQ. The Binet-Simon and Stanford-Binet offered a single score, global IQ, plus mental age (MA); the W-B offered verbal, performance, and full-scale IQs, along with a profile of scaled scores on 11 separate subtests (one of which, vocabulary, was an alternate and did not contribute to the IQs). The 1916 Stanford-Binet and its subsequent editions in 1937, 1960, and

1972 (coauthored by Maud Merrill) were routinely administered to children, adolescents, and adults; however, they were never standardized (normed) on adult populations. Consequently, when Wechsler published the W-B, standardized on children and adults (including older adults), he effectively developed the first real test of adult intelligence. And, in 1939, he replaced the ratio IQ that had become a staple in the Binet scales with the "deviation IQ." Ratio IQs were based on an old formula that compared mental age to chronological age and represented a "rubber yardstick" because 1 year's growth is quite different at age 5, 9, or 15; the outmoded formula also was not applicable to adults. By contrast, deviation IQs are standard scores with a mean of 100 and a standard deviation (SD) of 15 for all three IQs at all ages. They are derived from the concepts of the normal curve and standard deviations, which avoid problems associated with ratio IQs. Wasserman (2012) points out that "Wechsler deserves credit for popularizing the deviation IQ, although the Otis Self-Administering Tests and the Otis Group Intelligence Scale had already used similar deviation-based composite scores in the 1920s" (p. 35).

Wechsler's (1939) definition of intelligence has been widely quoted:

Intelligence is the aggregate or global capacity of the individual to act purposefully, to think rationally and to deal effectively with his environment. It is global because it characterizes the individual's behavior as a whole; it is an aggregate because it is composed of elements or abilities which, though not entirely independent, are qualitatively differentiable. By measurement of these abilities, we ultimately evaluate intelligence. But intelligence is not identical with the mere sum of these abilities, however inclusive. (p. 3)

In this definition, he shows the influence of Spearman's *g* on his theory but also makes it clear that there is more to intelligence than *g*. But Wechsler's lasting imprint was as a test developer, not as a theorist. And, ultimately, his greatest contribution may have been his clinical approach to the measurement of intelligence. When the Stanford-Binet reigned supreme prior to the

publication of the W-B, the main approach to test interpretation was *psychometric*, with the focus on the precise IQ, its percentile rank, the band of error surrounding the IQ, and group differences in mean IQ (e.g., urban versus rural children); the main book on Stanford-Binet interpretation was written by McNemar (1942), a statistician. Wechsler changed all that. He believed that intelligence was part of personality and that personality variables affected how a person performed on an IQ test. He encouraged examiners to interpret the IQs and subtest scaled scores within the context of the clinical behaviors observed during the evaluation and the reasons for referral (emotional disturbance, dementia) and to interpret responses to specific items (e.g., verbal answers on social comprehension questions) in terms of their clinical content. Thanks in large part to his experiences as an examiner during wartime, his clinical acumen, and his responsibilities at Bellevue Hospital, which brought him into one-on-one contact with individual patients from diverse backgrounds with an array of diagnoses, Wechsler (in conjunction with innovators such as Rapaport et al. 1945) changed IQ measurement from *psychometric testing* to *clinical assessment*. That distinction still characterizes the training of clinical psychologists and neuropsychologists worldwide.

An immediate benefit of the Wechsler approach to IQ testing was the large number of reliable and valid scores yielded by his tests – three IQs and an array of a dozen or so scaled scores on separate subtests. The full-scale IQ provides a global measure of intelligence (as was provided by the Stanford-Binet). However, the addition of separate verbal and performance IQs allowed examiners to determine whether a person was better able to express his or her intelligence via verbal comprehension and expression or nonverbally via the manipulation of concrete materials. And the subtest scaled scores – standard scores with a mean of 10 and SD of 3 for all subtests at all ages – permitted clinicians to examine a person's profile of strengths and weaknesses on cognitive tasks such as information, similarities, block design, and picture arrangement.

The separate IQs and the profile of scaled scores provided a breakthrough for researchers and clinicians who needed to go beyond a single, global IQ to better understand a person's abilities and disabilities. The global IQ masked areas of strength and weakness. The W-B, and later the 1949 Wechsler Intelligence Scale for Children (WISC) and 1955 Wechsler Adult Intelligence Scale (WAIS), spawned state-of-the-art research with patients diagnosed with neurological impairment in the left versus right hemisphere (Reitan 1955; Meyer and Jones 1957), with children and adolescents referred for reading and learning disabilities (Bannatyne 1971), and with individuals diagnosed with autism (Murata et al. 1974; Wassing 1965). The comparison of verbal IQ with performance IQ (V-P discrepancy) was especially crucial for understanding the strengths and weaknesses of individuals with left-hemisphere damage ($P > V$), right-hemisphere damage ($V > P$), and autism ($P > V$). The separate IQs also contributed mightily to understanding the differential effects of aging on intelligence (Feingold 1950; Jarvik et al. 1962) and to the theory of fluid and crystallized intelligence (Horn and Cattell 1966).

The profile of scaled scores was found to be particularly useful for identifying children with reading disabilities and for understanding the language problems of individuals with autism or other language disorders (e.g., comparing their performance on verbal subtests that required much verbal expression, such as vocabulary, with their performance on tasks like information that required little verbal expression). For reviews of studies on Wechsler profiles for children and adults diagnosed with autism spectrum disorders, including Asperger's disorder, consult Barnhill et al. (2000), Klin et al. (2000), and Lichtenberger and Greenberg (2009).

The Stanford-Binet remained the most popular IQ test into the early 1960s, even after the WISC and WAIS were published. However, as the fields of learning disabilities, neuropsychological assessment, and autism began to grow exponentially during the 1960s and started to dominate clinical practice in schools and clinics, Wechsler's scales surpassed the Stanford-Binet. By the time

the WISC revision (WISC-R) was published in 1974, Wechsler's scales for children and adults were by far number one in the United States, and his scales have remained number one, worldwide, into the second decade of the twenty-first century. The WISC-IV and WAIS-IV are dominant, and the Wechsler Preschool and Primary Scale of Intelligence, Third Edition (WPPSI-III) is a popular choice for assessing young children. Fig. 2 shows the history of Wechsler's scales, from the 1939 W-B Form I to the 2008 WAIS-IV. Not shown in the figure is Wechsler's widely used *memory* test for adolescents and adults, the Wechsler Memory Scale (WMS), now in its fourth edition (WMS-IV).

"For his master's thesis completed in 1917, Wechsler patched together a clinical memory battery from existing published and unpublished tests [...] . . . a pattern he was later to follow with intelligence tests" (Wasserman 2012, p. 31). But his approach to test construction does not diminish his amazing innovations, including his insistence (in a Binet-dominated world) that nonverbal assessment must accompany verbal assessment to yield a truly global measure of a person's intelligence or his assertions that IQs and scaled-score profiles are only meaningful when interpreted within a rich clinical context, points that he introduced to the world with eloquence in his landmark articles and books (e.g., Wechsler 1928, 1930, 1935, 1939, 1944, 1950, 1958, 1971, 1975). And his genius did not diminish with age. When

I worked with Wechsler on the revision of the WISC in the early 1970s, "he was in his mid 1970s and as active and involved in his tests as ever. He showed me notebooks filled with new items, including comic strips he had cut out from newspapers to adapt for nonverbal test items. With his own tool kit, he had constructed a variety of wooden dolls and formboards, always in search of new ways of measuring mental ability." (Kaufman 2009b, p. 34)

He even analyzed himself: "After completing his fellowship at the Sorbonne, Wechsler traveled through France, Switzerland, and Italy, before reluctantly returning to the United States.... His ambivalence about returning, as disclosed to Edwards (1974), was reflected in his 1922 paper on the psychopathology of indecision" (Wasserman 2012, p. 33).

And his ideas were consistently decades, even generations, ahead of his time. Wechsler (1935) was an early advocate of measuring adaptive behavior skills, urging that daily behaviors, social demands, and functional living skills be considered alongside IQ test results before assigning a mental deficiency diagnosis. As J. D. Wasserman (personal communication, July 27, 2011) pointed out, Wechsler's approach is "entirely congruent with even contemporary standards for diagnosing intellectual disability (Schalock and The AAIDD Ad Hoc Committee on Terminology and Classification 2010)." He also reflected current philosophies by urging caution and

sensitivity about the consequences of applying labels such as mental deficiency and genius based solely on IQ, because “Too much is at stake” (Wechsler 1971, p. 54).

In Wechsler’s lifetime, his scales were organized around the distinction between V and P IQs. Subsequent versions have emphasized four indexes, two of which replaced V IQ and P IQ (verbal comprehension index, or VCI, and perceptual reasoning index, or PRI), and two of which were new: working memory index (WMI) and processing speed index (PSI). L. G. Weiss (personal communication, July 26, 2011) noted that Wechsler’s “early notions on the importance of mental manipulation (Arithmetic/Digit Span) and mental speed (Digit Symbol/Coding) were borne out by modern research and subsequently fleshed out into WMI and PSI, which increased his test’s sensitivity to clinical disorders and extended his influence well into the twenty-first century.”

In a 1976 interview, Wechsler credited Woodworth and E. L. Thorndike as contributing most to his intellectual development, and he also praised Augusta Bronner and William Healy for refining his clinical skills: “they were both wonderful clinicians and they were the first, as I recall, who had discussions of every individual case at which first the social worker would present her history, then the psychiatrist, then the psychologist, and they either praised the individual and so forth on the basis of these conferences” (Hargus and Wasserman 1993).

- Berlin, Germany
- 1878

Landmark Clinical, Scientific, and Professional Contributions

Wernicke is best known for his theory of aphasia, publishing a manuscript entitled “The Aphasia Symptom Complex” in 1874 when he was 26 years old. This publication catapulted Wernicke as the leader in aphasia research. Several years later, Wernicke published a textbook on brain diseases. In this book, he described a condition called “pseudoencephalitic haemorrhagica superior,” later to be known as “Wernicke’s encephalopathy.” In addition to his work on aphasia, Wernicke pioneered a technique for drainage of cerebral spinal fluid in patients with hydrocephalus.

Short Biography

Karl Wernicke was born in Wroclaw, Poland, in 1848. He studied medicine at the University of Breslau. Upon completion of his medical degree, Wernicke completed training in psychiatry. Wernicke worked under and collaborated with a variety of neuroscientists and neuropsychiatrists prior to designing his theory of aphasia. Wernicke discovered that damage to the left posterior, superior temporal gyrus resulted in deficits in language comprehension. This region of the brain is commonly referred to as “Wernicke’s Area,” and the syndrome in which damage to this region of the brain occurs often results in what is now known as “Wernicke’s aphasia.” Following Wernicke’s publication of his aphasia manuscript, he was appointed to the Department of Psychiatry and Nervous Disease of the Berlin Charité Hospital in 1878. During his time at the hospital, there was a significant discord between Wernicke and the administration. This conflict

forced Wernicke into private practice. Despite this conflict, Wernicke remained active in both clinical care and research activities. He continued to publish and pioneer new techniques in the field of neuroscience. In 1885, Wernicke became Professor of Psychiatry at Breslau Psychiatric Hospital at the university where he opened an outpatient clinic for individuals with neurological pathology. Unfortunately, there was tension between Wernicke and the hospital. Wernicke was ultimately forced to leave his position. In 1904, Wernicke was offered the Chair of Psychiatry and Nervous Diseases at University of Halle. Wernicke continued his work in neurological disease at the university until his untimely death due to a bicycle accident in 1905 at the age of 58. Although Wernicke died relatively early, his work continues to have significant influence in the fields of neurology and psychiatry.

Short Description or Definition

Wernicke's aphasia is a condition that is associated with damage to Brodmann area 22 in the left posterior superior temporal gyrus. The disorder is named for Karl Wernicke, the individual who is credited with first recognizing it. Wernicke's aphasia is also known as fluent aphasia or receptive aphasia as deficits tend to be in the content of the spoken message rather than speech output. As such, individuals with Wernicke's aphasia use sentences that are intact in terms of syntax, grammar, rate of speaking, and prosody but demonstrate difficulties with content such as vocabulary. Error patterns include word substitutions, additions, and difficulties with word order. In addition, patients demonstrate extreme difficulty in comprehending both what they themselves are saying and what is being said to them.

Categorization

Wernicke's aphasia is considered a fluent aphasia within larger aphasia classification systems.

Epidemiology

Estimates of the prevalence of Wernicke's aphasia in the larger population are largely unknown, though it has been estimated that 80,000 people develop aphasia in the United States each year.

Clinical Expression and Pathophysiology

Wernicke's aphasia often occurs as the result of damage to left posterior superior temporal gyrus. The condition manifests itself as a fluent aphasia in which an individual demonstrates relatively fluent language output. However, this output is characterized by the use of extra words, "made-up" words, or words that are out of order. In addition, language comprehension skills are largely impaired in individuals with Wernicke's aphasia.

Evaluation and Differential Diagnosis

Please see ► [“Aphasia”](#).

Treatment

Treatment for Wernicke's aphasia is often multifaceted and is typically individualized based on the patient's profile of strengths and needs. Individuals with aphasia often enroll in formal speech-language therapy to address functional communication in a variety of settings in which they are expected to communicate. Therapy goals are focused on maximizing the individual's ability to communicate effectively with peers and family members, given residual strengths. For individuals with Wernicke's aphasia, it is critical to support both comprehension and production; although speech/language output is fluent, patients often do not comprehend what they are saying or what is being said to them.

Although some individuals recover completely, individuals with aphasia often experience lifelong deficits. In these cases, family member and patient support groups are often a critical piece of the therapeutic process as the patient and family learn to manage their new situation.

Wide Range Assessment of Memory and Learning (WRAML)

[WRAML-2](#); [WRAML2](#)

Description

The WRAML2 (Sheslow and Adams 2003) is a clinical assessment instrument designed to evaluate memory and learning in children and adults (ages 5–90 years). The test is administered individually

with the examiner presenting items and recording responses. Three index scores are derived from six core subtests assessing verbal memory, visual memory, and attention-concentration. In addition, a general memory standard score can be calculated. Supplementary subtests provide the opportunity to assess working memory, recognition memory, and delayed recall. A more brief “memory screening” option is also available.

Content

In all, the WRAML2 is comprised of 6 core subtests and 11 optional subtests, generating 9 possible global index scores. Several subtests from the original WRAML (Sheslow and Adams 1990) are now optional (e.g., Sentence Memory) or limited to a specific age group (e.g., Sound Symbol for ages 5–8 years; Verbal Working Memory and Symbolic Working Memory for individuals 9 years of age and older). New additions include two subtests to assess working memory and four recognition memory tasks. In addition, items have been updated on existing subtests, such as contemporary full-color scenes on the Picture Memory subtest, revised stories in story memory (lengthened to accommodate adults), and more contemporary language on the Sentence Memory subtest. One subtest from the WRAML, Visual Learning, has been eliminated.

The core battery can be individually administered in under an hour, and a memory screening form, composed of four subtests, requires 10–15 min administration time and correlates highly ($r = .91$) with the full test.

The WRAML2 yields standard scores, scaled scores, and percentiles. The test also provides several qualitative analyses scores. Age equivalents are available for the child and preadolescent age groups. Subtest raw scores are converted into scaled scores based on a mean of 10 and standard deviation of 3. Index scores are derived from the sum of the relevant subtest scores and reported with a mean of 100 and standard deviation of 15 for age-based performance comparisons. A profile grid is provided allowing the examiner to plot scores across subtests and indexes for interpretation. A computerized scoring program is also available.

The global domains (underlined) and subtests (*italicized*) of the WRAML2 are described briefly below:

- *Verbal Memory Index*. An index of how well the individual is able to learn and recall both meaningful verbal information and relatively rote verbal information.
- *Story Memory Subtest*. A measure of memory for contextualized or meaningful verbal information. Two short stories are read to the examinee; following each story, the examinee is asked to orally recall as much of the story as he/she can remember.
- *Verbal Learning Subtest*. A measure of how well the individual actively learns, with practice opportunities, and is able to recall meaningful verbal information that is without context. The evaluator reads a list of common, single-syllable words followed by an immediate free recall trial; this list is repeated across four trials.
- *Visual Memory Index*. An index of how well the individual can learn and recall both meaningful (i.e., pictorial) and minimally related, rote (i.e., design) visual information.
- *Design Memory Subtest*. A measure of memory for visual material that is minimally meaningful. Five cards, each with an array of geometric shapes, are exposed, and then after a brief delay, the examinee is asked to draw what is remembered.
- *Picture Memory Subtest*. A measure of nonverbal immediate memory for contextualized information or meaningful information. The examinee is shown a colorful, everyday scene that he/she can scan for 10 s before it is removed. Then a similar alternate scene is immediately presented, and the participant must determine the elements that have been moved, changed, or added.
- *Attention/Concentration Index*. An index of how well the individual can learn and recall relatively nonmeaningful rote, sequential information. The tasks comprising this index require brief attentional demands and/or immediate rote recall abilities.
- *Finger Windows Subtest*. A measure of nonverbal, rote sequential recall; the examinee is asked to repeat gradually more difficult visual sequential patterns demonstrated by the examiner.
- *Number Letter Subtest*. A measure of auditory, rote sequential recall; the examinee is asked to repeat a series of items consisting of progressively longer number and letter sequences that are dictated by the examiner.
- *General Memory Index*. An index of overall memory functioning derived from performance on the six core subtests above.
- *Working Memory Index*. An index of how well the individual can operate on (e.g., add to, reorganize, or manipulate) and retain information that is held in the short-term memory buffer (i.e., in an active, online state).
- *Verbal Working Memory* (for ages 9 years and older). A measure of how well an individual retains information that is manipulated while it is in short-term memory. The examinee listens to a list of nouns that are both animals and nonanimals and, immediately thereafter, is required to recall the words in a specified reorganized order.
- *Symbolic Working Memory* (for ages 9 years and older). A measure of how well a person actively operates on and retains symbolic information (e.g., numbers, letters) prior to recall. Memory and attention are important for this task, and executive skills are also involved in finding an appropriate learning strategy.
- *Verbal Recognition*. An index of how well specific verbal information that was presented previously during this testing session is recognized following a short delay (15–20 min).
- *Story Memory Recognition*. A measure of recognition memory using a multiple-choice format with questions from each previously presented story. A comparison can be made between free recall (in the immediate recall and the delayed recall story memory formats) and recognition.
- *Verbal Learning Recognition*. Provides a measure of recognition recall of verbal information

presented previously as part of the verbal learning subtest.

- *Visual Recognition.* An index of how well the individual can recognize specific nonverbal or visual information that was presented previously in the session (i.e., approximately 15–20 min earlier).
- *Design Memory Recognition.* A measure of recognition recall of visual information that was viewed approximately 20 min earlier. The examinee is asked to look at and distinguish between designs that were and were not presented earlier in the testing session. It involves attention to visual detail and executive skills.
- *Picture Memory Recognition.* A measure of recognition of previously presented meaningful visual information or contextualized visual information, such as that found in pictures, in scenes, or in the environment.
- *General Recognition.* In contrast to memory retrieval as represented in the verbal memory index and the visual memory index scores, the general recognition index provides an estimate of how well the individual can *recognize* specific verbal and visual information that was presented previously (i.e., approximately 15–20 min earlier). This information is relevant to initial encoding strategies.
- *Delay Recall.* No global index score is provided for delayed recall; however, for each individual subtest, retention scores are generated providing a measure of memory decay over time.
- *Story Memory Delay Recall.* A measure of memory for a meaningful verbal narrative over a 10–15-min delayed interval.
- *Verbal Learning Delay Recall.* A measure of memory retrieval after the initial learning of new verbal information (approximately 15 min after initial learning).
- *Sound Symbol Delay Recall* (for ages 8 and younger). A measure of memory retrieval for paired associates (visual-auditory verbal) over a short delay.
- *Additional Subtests*
- *Sentence Memory.* A measure of immediate verbal memory skills similar to those needed

to follow novel verbal directions or to relay a brief phone message accurately. On this subtest, the examinee is required to repeat dictated single sentences of increasing length.

- *Sound Symbol* (for ages 8 and younger). A measure of paired-associate memory and learning. The examiner shows a symbol appearing on a page of the easel booklet and then identifies its sound that the child then repeats. The child is asked to try to recall that same sound when he/she sees the same symbol.

Historical Background

The first edition of the WRAML was published in 1990, filling a need for a comprehensive well-normed battery assessing children's memory functioning. The original WRAML was normed for children ages 5–17 years. The second edition, published in 2003, provides updated and extended norms (ages 5–90 years) as well as new test material. Focus groups were used to obtain first-hand information about improving the test; an item “tryout” was followed by a standardization program. Only one subtest (Visual Learning) was eliminated in the revision.

Psychometric Data

Norms. The standardization edition of the WRAML2 was administered to 1200 individuals across 22 states, representing different geographical regions. A national stratified sampling technique was used, controlling for age, sex, race, region, and education, with efforts to make the normative sample mirror the 2001 US Census. Slight variations in the normative sample from census data were corrected with a statistical weighting procedure.

Reliability. Scores from the WRAML2 are highly reliable. Reliability coefficients for the core battery Verbal Memory Index, Visual Memory Index, and attention/Concentration Index are .92, .89, and .86A, respectively. The alpha reliability for the general index is .93. Internal

consistency for the six core subtests is also shown to be very good, with Cronbach's alpha coefficients ranging from .82 to .96. The range is wider for the optional subtests (.63–.96). Test-retest reliability indicates a substantial learning effect from one test time to another (median administration lag of 49 days) with an overall gain of approximately +1 scaled score on subtests. Therefore, reliability correlations are lower with correlations between .53 and .85 for core subtests and indexes and .47 to .80 for optional subtests. Inter-rater reliability was quite high (.98).

Validity. Internal validity was assessed via examination of item content, subtest intercorrelations, exploratory factor analyses, confirmatory factor analysis, and differential item functioning. Item separation reliabilities, indicating how well the items define the variable being measured, were high (.90–1.00 for all subtests). Intercorrelations of the WRAML2 indexes and subtests were high for the older group (9 years to adult) but more variable in younger children. Results from factor analysis studies supported the internal validity of the WRAML2.

External validity was examined by comparing scores on the WRAML2 with related memory and learning measures, such as the Wechsler Memory Scale-III (WMS-III), Children's Memory Scale (CMS), and the California Verbal Learning Test-II (CVLT-II). Correlations were moderate (e.g., $r = .60$ for the WRAML2 General Memory Index score and the WMS-III General Memory Index score and $r = .49$ for the CMS). Moderate correlations were also found with cognitive measures (i.e., Wechsler Adult Intelligence Scale [WAIS-III] and the Wechsler Intelligence Scale for Children, Third Edition [WISC-II]) and with achievement tests (i.e., Wide Range Achievement Test 3 [WRAT3], and the Woodcock-Johnson, Third Edition [WJ-III] Tests of Achievement).

attentional difficulties, administration of the WRAML2 may help to clarify the contributions of attention, learning, and/or memory problems. This measure may also be used to assess memory impairment following head injury. The manual contains information about small studies involving learning disabled children and adults with traumatic brain injury, Alzheimer's disease, and alcohol abuse, suggesting WRAML2 sensitivity to these influences.

Landmark Clinical, Scientific, and Professional Contributions

In 1979, Lorna Wing and her Maudsley colleague, Judith Gould, published a landmark study of 173 children in Camberwell, South London, who had autistic features or had an IQ of under 50, or both. As Wing told Adam Feinstein in 2009, there were certainly some children who beautifully fitted Leo Kanner's 1943 criteria for autism, "but there was a huge collection in the middle who could not be put into either category. Very few fitted Asperger's syndrome, because they virtually all had an IQ of under 60 and none were mainstreamed." From their findings, Wing and Gould concluded that there was clearly a broader autism phenotype. This inspired them to introduce the concept of the triad of impairments in autism: deficits in social relations, communication, and imagination, a concept still used by diagnosticians today. Some researchers, like Francesca Happé at London's Institute of Psychiatry, maintain that, while the Wing-Gould version does indeed form

a true unitary triad, the DSM-IV and ID-10 notion of repetitive behavior – rather than imagination – as the third element has meant that the triad becomes "fractionable" (in the sense that the three elements may have separate causes at the genetic, neurological, and cognitive levels).

Short Biography

Dr. Lorna Wing, FRCPsych, born on October 7, 1928, is an English psychiatrist and physician and one of the world's leading autism authorities.

As a result of having an autistic daughter, Suzie, she became involved in researching developmental disorders, particularly autism spectrum disorders. She joined with other parents of autistic children to found the National Autistic Society (NAS) in the United Kingdom in 1962. She currently works part time as a consultant psychiatrist at the NAS Centre for Social and Communication Disorders at Elliot House.

Wing is the author of many books and academic papers, including *Asperger's Syndrome: a Clinical Account*, a 1981 academic paper that popularized the research of Hans Asperger and introduced the term "Asperger's syndrome." Although groundbreaking and influential, Wing herself cautioned in her 1981 paper that "it must be pointed out that the people described by the present author all had problems of adjustment or superimposed psychiatric illnesses severe enough to necessitate referral to a psychiatric clinic ... (and) the series described here is probably biased towards those with more severe handicaps."

Winkleman v. Parma City School District (2007 Rights Under IDEA)

Allison Kahl
New York University School of Law, New York,
NY, USA

Definition

In General

In this case, the U.S. Supreme Court held that the Individuals with Disabilities Education Act (IDEA) grants parents independent, enforceable

rights. Parents are not limited to bringing claims on behalf of their child or claims based on procedural and reimbursement-related matters, but may sue to enforce their own rights to a “free appropriate public education” (FAPE) for their children.

The Supreme Court based its decision on statutory analysis, legislative intent, and policy considerations (Steiner 2008, p. 1172). IDEA entitles parents to voice their concerns as part of the individualized education program and (IEP) team as well as to submit a complaint concerning the adequacy of the education, the IEP’s construction, or other related matters. “Any party aggrieved,” including a parent, also has the right to bring a civil action based on that complaint. Additionally, IDEA’s express purpose is to protect “the rights of children with disabilities and parents of such children.” The court held that IDEA was intended to confer separate rights to parents of children with disabilities.

Implications for ASD Students

Since parents have their own independent rights under IDEA, a parent of a student with an autism spectrum disorder (added to IDEA’s list of disabilities in 1991), whether or not he or she can afford an attorney, now has the right to enforce his or her rights as a parent to obtain a quality education for their child. This makes IDEA a more substantive and robust reform of special education law (McNeal).

Litigation Strategies

While the decision appears clear-cut, it has led to significant confusion and problems in the lower courts (Zirkel 2009, p. 1). It triggers many larger issues, which are not resolved by the court. For example, there is no clear distinction between the child’s rights under IDEA and the rights of the parents and no sense of what remedy there is for a violation of parental rights. In addition, there is a concern that this decision allows parents to represent their children’s substantive interests pro se which violates common law principles and public policy considerations (Steiner 2008, p. 1181). These considerations seek to ensure that children are represented by those that can best represent them. Still, the decision does clearly allow parents

to lower the potential costs of litigation by suing without representation.

Description

The Wechsler Intelligence Scale for Children–Fifth Edition (WISC–V) is a standardized clinical assessment instrument. The clinical instrument assesses general cognitive abilities in children ages 6–16 years 11 months; specifically, it assesses general problem-solving and reasoning skills in verbal, nonverbal, and visual domains, as

well as working memory and processing speed in children and adolescents. This test is individually administered, scored, and interpreted by a trained clinician. Administration typically can be completed within 60–90 min. The WISC–V results in standard scores according to age-referenced norms from a national sample; standard scores can be calculated for specific cognitive indices as well as one or more global indicators of cognitive ability including a Full-Scale Intelligence Quotient (Full-Scale IQ).

The WISC–V framework consists of a Full-Scale Index (or Full-Scale IQ), in addition to primary, ancillary, and complementary indices that are made up of various combinations of primary, secondary, and complementary subtests that are the actual tasks administered by the clinician to the individual. The primary indices that form the core of the cognitive measure are Verbal Comprehension (VCI), Visual Spatial (VSI), Fluid Reasoning (FRI), Working Memory (WMI), and Processing Speed (PSI). These indices are the result of a five-factor model of cognitive abilities (Wechsler 2014). The five primary indices are derived from ten primary subtests: Vocabulary, Similarities, Block Design, Visual Puzzles, Matrix Reasoning, Figure Weights, Digit Span, Picture Span, Coding, and Symbol Search. Two primary subtests make up each index score, with complementary subtests rounding out a fuller measurement of the cognitive abilities of each index area.

The Verbal Comprehension Index (VCI) is comprised of the primary subtests, Similarities and Vocabulary, and the secondary subtests, Information and Comprehension. The VCI subtests assess an individual's ability to access and apply acquired word knowledge. The application of this knowledge involves verbal concept formation, reasoning, and expression. The Visual Spatial Index (VSI), which is comprised of two primary subtests, Block Design and Visual Puzzles, assesses an individual's ability to evaluate visual details and to understand visual spatial relationships to construct geometric designs from a model. The ability to construct designs requires visual spatial reasoning, integration and synthesis of part-whole relationships, attentiveness to visual detail, and visual-motor integration. The Fluid Reasoning Index (FRI) measures a person's

ability to detect the underlying conceptual relationships among visual objects and to use reasoning to identify and apply rules. Identification and application of conceptual relationships require inductive and quantitative reasoning, broad visual intelligence, simultaneous processing, and abstract thinking. The FRI is comprised of two primary subtests, Matrix Reasoning and Figure Weights, and two secondary subtests, Picture Concepts and Arithmetic. The Working Memory Index (WMI) assesses the ability to register, maintain, and manipulate visual information through the Picture Span subtest and auditory information through the Digit Span subtest. Letter–Number sequencing is a secondary subtest within the WMI that further assesses working memory through an auditory information task. The last primary index, Processing Speed, measures an individual's speed and accuracy of visual identification, decision-making, and decision implementation. Performance on the two primary PSI subtests, Coding and Symbol Search, and one secondary subtest, Cancellation, is related to visual scanning, visual discrimination, short-term visual memory, visuomotor coordination, and concentration.

In total, the WISC–V consists of 21 subtests, only ten of which are considered primary subtests and essential to calculating primary index scores. Seven of the ten primary subtests combine to arrive at the Full-Scale IQ (Similarities, Vocabulary, Block Design, Matrix Reasoning, Figure Weights, Digit Span, and Coding). The remaining 11 subtests are considered secondary or complementary. Secondary subtests (Information, Picture Concepts, Letter–Number Sequencing, Cancellation, Comprehension, and Arithmetic) can be used as a substitute for a related primary subtest to calculate the Full-Scale IQ. Additionally, secondary subtests are recommended for administration in order to provide more in-depth information about a child's intellectual functioning and for clinical decision-making, as they make up ancillary index scales. Complementary subtests (Naming Speed Literacy, Naming Speed Quantity, Immediate Symbol Translation, Delayed Symbol Translation, and Recognition Symbol Translation) are not

designed as measures of intelligence but rather to aid in assessment of cognitive processing associated with academic learning. The Complementary subtests comprise the complementary index scales of Naming Speed, Symbol Translation, and Storage and Retrieval.

The WISC–V provides global indicators of cognitive functioning via the Full-Scale IQ, as well as ancillary indices, specifically, the Nonverbal Index, General Ability Index, and Cognitive Proficiency Index. The ancillary indices may be interpreted as a better estimate of a given child's overall cognitive abilities than the Full-Scale IQ based on the individual's performance profile. More specifically, when there is an unusually high amount of variability between subtest scores that comprise the Full-Scale IQ, this Index score is not considered to be a good measure of the child's global intellectual ability, and it is recommended that other global estimates of cognitive functioning be reported. The Nonverbal Index is a measure of general cognitive ability that minimizes expressive language demands. The General Ability Index is an estimate of cognitive ability that reduces emphasis on working memory and processing speed, and it is thought to be a more pure representation of crystallized intelligence, which is heavily based on language and previously learned information. Lastly, the Cognitive Proficiency Index is the summary index made up of the four working memory and processing speed subtests, thus providing a global estimate of a child's cognitive efficiency for manipulating and rapidly processing information.

Historical Background

Intelligence tests were first developed in the early 1900s to more objectively assess and quantify aspects of disability and mental illness, in addition to qualifications or capabilities of an individual. There are various theories and definitions of intelligence and thus various theories on how to measure cognitive functioning (Sattler 2008). David Wechsler (see ► [Wechsler, David](#)), the creator of the original Wechsler scales that have evolved into the current WISC–V, considered intelligence to be

a global factor. He designed his original intelligence scale to consider factors contributing to the effective intelligence of the individual with the overall IQ score representing an index of general mental ability. Thus, from its outset, the Wechsler intelligence scales are rooted in a factor theory of intelligence – espousing to the theory of a general intelligence that is comprised of multidimensional cognitive abilities.

Wechsler developed the Wechsler–Bellevue Intelligence Scale in 1939 for use with adults, and in 1949, the first edition of the Wechsler Intelligence Scale for Children (WISC; Wechsler 1949) was created as a downward extension of the Wechsler–Bellevue scale. The WISC was the first intelligence test created for use in children, specifically children ages 5 to 15 years old (Sattler 2008). The original scales consisted of 12 subtests, many of which remain on the current version in an updated form. The subtests were organized into Verbal and Performance scales resulting in a Verbal IQ (VIQ), Performance IQ (PIQ), and Full-Scale IQ. In 1974, the first revision was produced, the Wechsler Intelligence Scale for Children–Revised (WISC–R; Wechsler 1974). The revision changed the targeted age range for the instrument to 6- to 16-year-old children. After Wechsler’s death in 1982, Psych Corp produced subsequent editions of the WISC and continues to list David Wechsler as the author through the current version. The third edition (WISC–III; Wechsler 1991) was the first revision to introduce significant content and structure changes to the measure. A new subtest for processing speed was developed for the WISC–III, and the measure was organized into more specific indices of cognitive functioning beyond the overarching composites of VIQ, PIQ, and FSIQ: Verbal Comprehension (VCI), Perceptual Organization (POI), Freedom from Distractibility (FDI), and Processing Speed (PSI). The next revision, WISC–IV, was developed in 2003 (Wechsler 2003). The development of the WISC–IV again ushered in major changes to subtest content and structure including updated item content and scoring procedures. The original VIQ, PIQ, and FSIQ were dropped and formally replaced with the specific indices developed on the WISC–III that were revised to reflect the

cognitive abilities assessed by the WISC: the Verbal Comprehension Index (VCI); the Perceptual Reasoning Index (PRI), formally named Perceptual Organization; the Working Memory Index (WMI), formerly named the Freedom from Distractibility; and the Processing Speed Index (PSI).

The WISC–V is the most recent revision of the WISC. One of the major changes in the new edition is the update to the theoretical foundation of cognitive functioning and intellectual assessment through the use of a five-factor model of test structure. The transition from a four- to five-factor model was born from factor analytic research of the WISC–IV and the Wechsler Adult Intelligence Scale–Fourth Edition (WAIS–IV; Wechsler 2008) (Benson et al. 2010; Keith et al. 2006; Weiss et al. 2013a, b), as well confirmatory factor analysis studies in the development of the WISC–V content (Wechsler 2014). The former Perceptual Reasoning Index was replaced by two indices, the Fluid Reasoning Index (FRI) and the Visual Spatial Index (VSI), to more accurately parse out cognitive abilities assessed within the WISC–IV PRI. Thirteen subtests were retained from the WISC–IV (Block Design, Similarities, Matrix Reasoning, Digit Span, Coding, Vocabulary, Symbol Search, Information, Picture Concepts, Letter–Number Sequencing, Cancellation, Comprehension, and Arithmetic). Eight new subtests were added (Figure Weights, Visual Puzzles, Picture Span, Naming Speed Literacy, Naming Speed Quantity, Immediate Symbol Translation, Delayed Symbol Translation, and Recognition Symbol Translation) to expand the cognitive abilities assessed by the measure and round out existing indices, while two subtests (Word Reasoning and Picture Completion) were dropped due to redundancy and limited utility. Thus the WISC–V consists of 21 subtests compared to the 12 subtests of the original WISC (Wechsler 1949) and 15 subtests on its immediate predecessor, the WISC–IV (Wechsler 2003). Furthermore, additional Ancillary and Complementary Indices were introduced to provide clinicians the opportunity to more robustly assess various cognitive abilities with the use of a single intelligence test. The new edition also provides updated normative data for scoring, reduced language in instructions,

changes in subtest scoring procedures, additional process subscores for subtests, and changes to score terminology and qualitative descriptors. There is also the ability to conduct an ability–achievement discrepancy analysis for various standardized achievement tests. Finally, the WISC–V introduces the capability to administer the measure via an iPad.

Psychometric Data

The WISC–V is a norm-referenced test that has been standardized on a clearly defined group and scaled so that each score reflects a rank within the normative group. Therefore, children are evaluated on how their performance compares with other children in their age group from a representative sample of children. After each subtest is scored, raw points are summed and converted to scaled scores according to normative data. An IQ is then computed by comparing the sum of scaled scores with the scores earned by a representative sample of peers in the same age group. Performance on the WISC–V indices, including Full-Scale IQ, is measured by a Standard Score. Standard Scores on the WISC–V have a range of 40–160, a mean of 100, and a standard deviation of 15. The WISC–V provides qualitative descriptors for specific ranges of Standard Scores: Extremely High (score 130 and above), Very High (120–129), High Average (110–119), Average (90–109), Low Average (80–89), Very Low (70–79), and Extremely Low (69 and below).

The WISC–V provides updated normative data collected from a representative sample of 2200 children stratified on the demographic variables of age, sex, race/ethnicity, parent education level, and geographic region from the years 2013 to 2014. The normative sample included typically developing children and children from the following identified special groups: intellectually gifted, intellectual disability–mild/moderate severity, borderline intellectual functioning, specific learning disorder – reading/reading and written expression/mathematics, attention deficit/hyperactivity disorder, disruptive behavior, traumatic brain injury, English language learners, and autism spectrum disorder with/without language impairment. Performance from the standardization

sample was used to inform starting points, discontinuity rules, and base rates for process scores, and the resulting raw scores were used to establish age equivalents and the normative standard scores for subtest and index scores for the measure.

The reliability and validity of the WISC–V has been broadly studied and is generally accepted as good. Rigorous reliability and validity analysis was conducted during test development of the WISC–V. WISC–V subtests demonstrate consistent or improved reliability from WISC–IV reliability findings (Wechsler 2014). Reliability of index scores is comparable or equal to corresponding indices on the WISC–IV. Importantly, the test’s reliability remains strong for special populations. Test–retest reliability for subtests is deemed adequately stable, while the primary index scores, with the exception of the Fluid Reasoning Index, demonstrate good to excellent stability (Wechsler 2014). WISC–V Full-Scale IQ scores also demonstrate excellent stability across two testing points. The WISC–V boasts very high interrater reliability, particularly for subtest scoring that requires greater examiner judgment (e.g., Similarities, Vocabulary, Information, and Comprehension) (Wechsler 2014).

The WISC scales have a long history of validity research with each revision, and the WISC–V builds on the strong foundation of content and construct validity for measuring intelligence (Flanagan and Harrison 2012; Flanagan and Kaufman 2009; Sattler 2008). The new five-factor structure of the WISC–V was based on current developments in intelligence theory and assessment, as well as confirmatory factor analytic research that further validated the five-factor structure of the WISC–V (Benson et al. 2010; Keith et al. 2006; Weiss et al. 2013a, b). WISC–V IQ scores were shown to correlate well with other established measures of intelligence, as well as having expected associations with other measures of a child’s functioning, such as academic achievement, adaptive skills, and behavior (Wechsler, 2014). The WISC–V reliability and validity extends to children with ASD with and without language impairment. Importantly, although the WISC–V as an instrument is deemed a valid tool for measuring an individual’s cognitive ability, the examiner administering the test to a given child

must assess whether the scores on that particular test are valid for that child based on the child's presentation, environmental, and testing factors.

Clinical Uses

The purpose of assessment includes screening, diagnosis, problem-solving, counseling and rehabilitation, and progress evaluation (see Psychological Assessment) (Sattler 2008). The WISC–V is used to assess and quantify a child's cognitive functioning in both global terms (Full-Scale IQ) and more specific cognitive abilities thought to comprise overall intelligence (i.e., Verbal Comprehension, Fluid Reasoning, Visual Spatial, Working Memory, and Processing Speed). Results from the WISC–V allow a clinician to describe a child's present cognitive functioning in reference to his or her peer group and to identify the nature of specific cognitive deficits and strengths to inform diagnostic conceptualization, and intervention planning, and progress.

In terms of diagnostic utility, the WISC–V is often used to establish a diagnosis of intellectual disability based on Full-Scale IQ score or another global index of cognitive functioning; the WISC–V is used in conjunction with assessment of an individual's adaptive behavior using a separate instrument to establish the presence and severity of an intellectual disability. The WISC–V also holds specific clinical utility for individuals with ASD. Psychological assessment that includes cognitive assessment is deemed the clinical standard of practice in the assessment of ASD as outlined by the American Academy of Child and Adolescent Psychiatry (AACAP) (Volkmar et al. 2014). Cognitive testing in ASD assessment is indicated to contextualize a child's social-communication difficulties and behavioral functioning relative to their overall development, as well as to inform treatment planning (Volkmar et al. 2014). Furthermore, in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th Edition (DSM-5; APA 2013), diagnostic criteria and characterization for ASD include specifiers to describe a child's presentation, including level of intellectual functioning or impairment. Therefore, inclusion of a standardized intelligence measure, such as the WISC–V, is

essential to arrive at a comprehensive and complete diagnosis of ASD that includes use of specifiers and level of severity rating within the DSM-5 framework. Moving into treatment planning and service allocation, the WISC–V, or another standardized measure of intelligence, is often required as part of the documentation process to confirm and characterize a child's disability, including ASD. An assessment that includes cognitive testing is often required in order for a child and family to access related government-funded services at the national and state level. The Wechsler scales are widely accepted by government agencies as an established intelligence instrument for both children and adults.

It is important that clinical use of the WISC–V with children with ASD be undertaken by trained professionals who are knowledgeable about test content, competent in standardized administration and scoring procedures, and clinically sensitive to interpret the resulting scores with understanding of the strengths and weaknesses of the WISC–V in assessing this clinical subgroup. To enhance the clinical utility of the WISC–V, targeted analysis of test performance was conducted on children with ASD with and without language impairment (Wechsler 2014). Performance results for both special subgroups of children with ASD replicated cognitive data from previous iterations of the WISC, indicating the WISC–V continues to be sensitive to identifying and quantifying cognitive strengths and weaknesses of children with ASD. A common cognitive profile for children with ASD with language impairment is lower performance than typically developing peers across all primary indices of the WISC–V, with relatively weaker verbal task performance and relatively higher visual spatial task performance within their cognitive profiles. It is thought that children with ASD with language impairment perform lower on a unitary measure of intelligence (i.e., Full-Scale IQ) than matched typically developing children due to the greater global cognitive deficits associated with this ASD presentation (Klinger et al. 2012; Wechsler 2003, 2012, 2014). Children with ASD without language impairment tend to have WISC–V performance profiles that are relatively consistent with their matched typically developing peers, with the exception of a significantly lower score on the

Working Memory Index resulting in a lower Cognitive Proficiency Index score. Additionally, this clinical subgroup demonstrated greater differences at the subtest level compared to matched peers indicating deficits in working memory and processing speed tasks with subtle language weaknesses (Mayes and Calhoun 2008; Wechsler 2014). In general, it is considered sound clinical practice to deem test scores estimates or approximations of the domains assessed and never to focus exclusively on the child's test scores (Sattler 2008). Furthermore, there are various strategies a clinician can use when interpreting scores from the WISC–V, particularly in children with varied cognitive abilities (e.g., profile analysis, significant strengths and weaknesses relative to base rates, use of other global indicators of intelligence) (Sattler 2008). The WISC–V is typically used as one part of a multifaceted developmental or psychological assessment. Assessment conclusions and recommendations should be based on multiple sources of information obtained, and not based solely on the WISC–V.

Wisconsin Card Sorting Test (WCST)

Description

The Wisconsin Card Sorting Test (WCST) is a measure of executive function that is used both clinically and within research. The WCST requires the participant to sort a set of cards according to implicit rules and based on the limited corrective feedback provided by the examiner. The participant's responses can be analyzed to produce separate indices of sources of difficulty on the test. The value of the WCST, therefore, lies in its sensitivity for detecting and characterizing aspects of executive dysfunction.

The WCST consists of two identical sets of 64 response cards that differ on three possible perceptual sorting dimensions: color (red, blue, yellow, or green), form (crosses, circles, triangles, or stars), and number of figures (one, two, three, or four). Four target cards that represent the range of dimensions (one red triangle, two green stars, three yellow crosses, and four blue circles) are placed in a prescribed order in front of the participant and they are handed one set of the response cards. The participant is instructed to match each card in turn with one of the four target cards. The examiner has a preselected sorting dimension (color) that the participant has to deduce using corrective feedback (i.e., whether they are correct or incorrect on a given card sort). At no point is the participant explicitly told how the cards should be sorted. Once the participant has achieved ten consecutive correct matches the sorting dimension is changed by the examiner. The examiner makes no explicit reference to this change; rather, the participant needs to deduce the shift by using the corrective feedback. The test continues with a new sorting dimension being introduced (according to a prescribed order) each time the participant achieves ten consecutive correct matches. The test is completed when six sets of sorts have been successfully achieved or when the two sets of response cards have been used, whichever occurs sooner. During administration, each card sort is marked by the examiner for the dimensions that it matches (i.e., color, form, figure, others). Analysis of the participant's responses enables calculation of a range of scores. These include number of trials administered, total number of correct trials, number of errors (total,

perseverative, and non-perseverative), perseverative responses, conceptual level responses (an index of the participant's insight into the sorting principles), number of categories completed, trials to complete first category (an index of initial conceptualization before a shift in set is required), failure to maintain set (an index of the inability to maintain the correct sorting dimension), and learning to learn (an index of improved efficiency in deducing the correct sorting dimension).

Historical Background

The WCST was originally designed to measure abstract reasoning and cognitive set shifting in healthy adults (Berg 1948), but became popular within the clinical neuropsychological field for detecting frontal lobe dysfunction. Various iterations of the test have been published, some including significant differences in administration or scoring, which has made interpretation across studies difficult. The version of the manual published in 1981 (Heaton 1981) was presented as a definitive standardized version. This manual was revised and expanded in 1993 and is the basis of the description above (Heaton et al. 1993). This full version of the test should take between 20–30 min to administer. More recently, shorter versions of the WCST have been developed (Kongs et al. 2000; Schretlen 2010). Computerized versions, which are both administered and scored online, are also now available (Heaton and Staff 2003a, 2003b).

Psychometric Data

The manual produced by Heaton et al. (1993) includes detailed normative data for 899 individuals aged 6½–89 years. Normative tables provide T scores, standard scores, and percentile scores for percent and total error scores (total, perseverative, and non-perseverative) as well as the percent and total perseverative responses and percent conceptual level responses. Percentile ranges are available for the number of categories completed, trials to complete first category, failure to maintain set,

and learning to learn. Descriptive statistics are also available for adults with a range of cerebral lesions (frontal, frontal plus, diffuse, non-frontal) and for children and adolescents with cerebral lesions, traumatic brain injury, seizure disorder, attention deficit disorder, and reading disorder.

Clinical Uses

The profile of performance across the WCST is used to provide a nuanced measure of executive dysfunction. For example, the data provides information about the ability to learn and retain new information, perseveration, the ability to generate problem-solving strategies, concept formation, and conceptual set shifting. The test is used in a wide range of clinical populations where executive dysfunction might be present, including those with acquired brain injury, neurodegenerative disease, and schizophrenia.

Landmark Clinical, Scientific, and Professional Contributions

Dr. Wolff's clinical and scientific work centered on the responses to stress and the development of personality, particularly of children who were socially isolated. Her work on the concept of schizoid disorder was conducted just at the time of the groundswell of interest in Asperger's syndrome and other autism spectrum conditions. Her books *Children Under Stress* (Wolff 1969, 2nd edition 1981) and *Loners: The Life Path of Unusual Children* (Wolff 1995) are particularly notable. Her dedication to longitudinal follow-up of the children she had worked with enriched her research and publications. Her study of the children she originally termed schizoid noted that in

adulthood, many remained social impaired and a minority of cases had difficulties such as schizophrenia and other problems. She was the mentor to many students who became leaders in the field.

Short Biography

Sula Wolff, one of the founders of child psychiatry in Great Britain, was born in Berlin. Along with her family, she immigrated to the United Kingdom and enrolled at Oxford.

She studied medicine at Oxford and then served as a pediatrician before beginning training in psychiatry at the Maudsley Hospital and completed her training in Scotland. She also worked both in South Africa and the United States. She was the first child psychiatrist to work in South Africa. She began her long association with the Royal Hospital for Sick Children in Edinburgh in 1966. From 1947 to 1955 she held a range of appointments at various hospitals.

Description

The Woodcock Johnson, Fourth Edition (WJ-IV) is a comprehensive set of tests to assess intellectual ability, academic achievement, and oral language ability. The WJ-IV includes three batteries: (1) the WJ-IV Tests of Cognitive Abilities (WJ-IV Cog; Schrank et al. 2014d), which assess overall intellectual ability and specific cognitive abilities; (2) the WJ-IV Tests of Achievement (WJ-IV Ach; Schrank et al. 2014a), which assess academic achievement, and (3) the WJ-IV Tests of Oral Language (WJ-IV OL; Schrank et al. 2014b), which assess oral language. Each battery is composed of a number of subtests. The test items on any given subtest are ordered from easiest to most difficult, and the tests utilize basal and ceiling rules to limit the range of items to those best suited to the examinee’s ability level. All stimulus materials are presented in a stimulus book, with no use of manipulatives. Some subtests involve paper and pencil or listening to an audio recording. A complete description of subtests included in each of the batteries follows.

WJ-IV Cog Battery

The WJ-IV Cog battery is composed of eighteen subtests; ten of these make up the standard battery, while an additional eight make up the extended

battery (McGrew et al. 2014). The standard battery includes the following subtests:

Subtest 1: Oral vocabulary. This task includes two parts: synonyms and antonyms. It provides a measure of lexical knowledge and language development.

Subtest 2: Number series. On this task, the examinee is presented with a series of numbers and is required to determine the numerical pattern in order to identify the missing number. This is a measure of quantitative reasoning.

Subtest 3: Verbal attention. This subtest requires the examinee to listen to a series of animal names and digits and then answer specific questions regarding their sequence. This provides a measure of attentional control and auditory working memory.

Subtest 4: Letter-pattern matching. This is a 3-min task that requires the examinee to locate and circle identical letter patterns as quickly as possible. This subtest becomes increasingly difficult, moving from single- to four-letter patterns. This is a measure of perceptual speed.

Subtest 5: Phonological processing. This subtest consists of three parts: (1) word access, which requires the examinee to say a word that has a specific beginning, middle, or ending sound; (2) word fluency, which requires the examinee to name as many words that he/she can recall within 1 min; and (3) substitution, which requires the examinee to substitute part of a word to create a new word. It measures phonetic coding and the speed of lexical access.

Subtest 6: Story recall. In this subtest, the examinee listens to a story and then must answer questions about the story. This measures listening ability, narrative comprehension, and recall.

Subtest 7: Visualization. This task is composed of two parts: (1) spatial relations, where the examinee must determine which puzzle pieces create a target shape, and (2) block rotation, where the examinee is presented with a series of three-dimensional patterns and must identify which two patterns would match the target pattern when rotated. This provides a measure of visual processing.

Subtest 8: General information. In this subtest, the examinee is asked a set of “where” and “what” factual questions. This task measures acquired verbal knowledge.

Subtest 9: Concept formation. This task requires the examinee to identify the rule that determines why some shapes are inside a box and others are not (i.e., the rule may be that shapes are inside the box if they are both big and yellow). This is a measure of inductive reasoning and cognitive flexibility.

Subtest 10: Numbers reversed. On this task, the examiner recites a series of numbers, and the examinee must repeat them back in reverse order. This is a measure of working memory.

The WJ-IV Cog Extended Battery includes the following additional subtests:

Subtest 11: Number-pattern matching. This speeded task is similar to letter-pattern matching but requires the examinee to locate and circle pairs of identical numbers rather than letters. It increases in difficulty, moving from single- to triple-digit numbers, and has a 3-min time limit. This is another measure of perceptual speed.

Subtest 12: Nonword repetition. On this subtest, the examinee must listen to and repeat a series of nonsense words. It provides a measure of phonological processing, including auditory processing and working memory.

Subtest 13: Visual-auditory learning. On this task, the examinee is required to learn an association between words and pictures and then use this information to decode a string of pictures and identify the corresponding sentence. This task measures associative learning and memory.

Subtest 14: Picture recognition. On this task, the examinee is shown a picture or multiple pictures. The examinee is then asked to identify the picture(s) they just saw from another set of pictures. This task measures visual memory.

Subtest 15: Analysis-synthesis. In this task, the examinee is provided with a set of color “equations” as well as rules about color equivalencies (e.g., “black” is equivalent to “blue and yellow”). The examinee’s task is to determine

which colors are missing from an equation in order to make the two sides of the equation equal to one another. This task provides a measure of sequential reasoning and problem solving.

Subtest 16: Object-number sequencing. On this subtest, the examiner says list words including objects (animals and foods) and numbers. The examinee's task is to say the numbers first, in the order the examiner said them, and then the objects in the order the examiner said them. This task provides another measure of working memory.

Subtest 17: Pair cancellation. On this task, the examinee is asked to scan through a set of pictures on a page to identify a pair of items, which they must then circle. For example, they may be asked to circle any time they see a dog followed by a ball. This task measures attention and concentration.

Subtest 18: Memory for words. On this subtest, the examiner provides a set of words, and the examinee must repeat back the words in the same order in which he or she heard them. This provides a measure of memory span.

The WJ-IV Cog subtests are grouped into seven broad areas of ability (i.e., fluid reasoning, comprehension-knowledge, short-term working memory, cognitive processing speed, auditory processing, long-term retrieval, and visual processing). The fluid reasoning domain consists of two subtests: *number series*, which contributes to the quantitative reasoning subdomain, and *concept formation*. There are also two subtests within the comprehension-knowledge domain: *oral vocabulary*, which contributes to the vocabulary subdomain, and *general information*. In terms of short-term working memory, the two subtests (*verbal attention* and *numbers reversed*) fall within the cognitive efficiency subdomain. The cognitive processing speed domain is composed of two subtests: *letter-pattern matching*, which contributes to the perceptual speed and cognitive efficiency subdomains, and *pair cancellation*. Within the auditory processing domain, there are two subtests: *phonological processing* and *non-word repetition*. The long-term retrieval domain

includes the *story recall* and *visual-auditory learning* subtests. There are also two subtests (*visualization* and *picture recognition*) included in the visual processing domain.

WJ-IV Ach Battery

As is the case with the cognitive battery, the WJ-IV Ach includes both a standard and extended battery. The standard battery includes 11 subtests, while the extended battery includes an additional 9 subtests (McGrew et al. 2014).

The WJ-IV Ach Standard Battery includes the following subtests:

Subtest 1: Letter-word identification. On this subtest, the examinee is asked to name letters and read written words. This task measures reading decoding and sight word recognition.

Subtest 2: Applied problems. This is a paper-and-pencil task in which the examinee must solve mathematical "word problems." This task measures quantitative reasoning, math achievement, and math knowledge.

Subtest 3: Spelling. In this task, the examinee is asked to write dictated letters and words. This provides a measure of spelling ability.

Subtest 4: Passage comprehension. On this subtest, the examinee reads a written passage and must "fill in the blank" by supplying a word that is missing from the sentence or paragraph. This measures reading comprehension and verbal language comprehension.

Subtest 5: Calculation. This subtest is a paper and pencil computation task, in which the examinee must complete mathematical computations ranging from simple addition to calculus. This provides a measure of mathematical achievement.

Subtest 6: Writing samples. On this subtest, the examinee must write sentences based on supplied instructions. This provides a measure of writing ability.

Subtest 7: Word attack. On this subtest, the examinee is asked to read and pronounce nonsense words. This provides a measure of reading decoding and phonetic coding.

Subtest 8: Oral reading. This task requires the examinee to read sentences of increasing

difficulty out loud to the examiner. This is a measure of reading accuracy and prosody.

Subtest 9: Sentence reading fluency. On this task, the examinee must read simple sentences and answer “yes” or “no” to indicate whether the statement is accurate (i.e., to ensure comprehension) within a 3-min time limit. This task provides a measure of reading speed.

Subtest 10: Math facts fluency. On this subtest, the examinee must complete simple paper-and-pencil calculations as quickly as possible within a 3-min time limit. This measures math achievement and numerical facility.

Subtest 11: Sentence writing fluency. In this task, the examinee must write as many sentences (using three provided words) as possible within a 5-min time limit. This provides a measure of writing speed.

The WJ-IV Ach Extended Battery includes the following subtests:

Subtest 12: Reading recall. In this subtest, the examinee reads a story silently and then must recite the story to the examiner. This measures narrative comprehension and recall.

Subtest 13: Number matrices. On this task, the examinee is presented with a number matrix and must solve for the missing number. This provides a measure of quantitative reasoning.

Subtest 14: Editing. On this subtest, the examinee is asked to orally provide a correction for errors in writing. This task measures language development and English usage.

Subtest 15: Word reading fluency. This task requires the examinee to locate and circle words that go together as quickly as possible. This measures word knowledge and semantic fluency.

Subtest 16: Spelling of sounds. On this task, the examinee is asked to write down the spelling of nonsense words heard orally. This provides a measure of spelling ability and phonetic coding and analysis.

Subtest 17: Reading vocabulary. On this task, the examinee is asked to provide synonyms and antonyms. This task measures verbal language comprehension and lexical knowledge.

Subtest 18: Science. This task involves answering factual questions to measure the examinee’s knowledge of the sciences (i.e., anatomy, biology, chemistry, geology, medicine, and physics).

Subtest 19: Social studies. This task involves answering factual questions to measure the examinee’s knowledge of history, economics, geography, government, and psychology.

Subtest 20: Humanities. This task involves answering factual questions to assess the examinee’s knowledge of art, music, and literature.

Just as the WJ-IV Cog subtests are grouped into areas of broad ability, the WJ-IV Ach subtests are grouped into curricular areas (reading, mathematics, written language, and academic knowledge). Within the reading domain are four subdomains: (1) basic reading skills (composed of the *letter-word identification* and *word attack* subtests), (2) reading comprehension (composed of the *passage comprehension* and *reading vocabulary* subtests), (3) reading fluency (composed of the *oral reading* and *sentence reading fluency* subtests), and (4) reading rate (composed of the *sentence reading fluency* and *word reading fluency* subtests). The Mathematics domain contains two subdomains: (1) math calculation skills (composed of the *calculation* subtest and the *math facts fluency* subtest) and (2) math problem solving (composed of the *applied problems* and *number matrices* subtests). The written language domain also includes two subdomains: (1) basic writing skills (composed of the *spelling* and *editing* subtests) and (2) written expression (composed of the *writing samples* and *sentence writing fluency* subtests). The Academic Knowledge domain does not include subdomains and is composed of the *science*, *social studies*, and *humanities* subtests. The remaining subtests are considered supplemental subtests. The WJ-IV Ach also includes additional cross-cluster domains.

WJ-IV OL Battery

The WJ-IV OL battery consists of twelve subtests, including three subtests for English-Spanish

bilingual individuals (McGrew et al. 2014). The battery includes the following subtests:

Subtest 1: Picture vocabulary. On this task, the examinee is asked to name or label a picture (or point to a picture that the examiner named). This subtest measures language development and lexical knowledge.

Subtest 2: Oral comprehension. This task involves listening to passages and identifying the missing words. This task measures listening ability as well as lexical knowledge and language development.

Subtest 3: Segmentation. This task requires the examinee to break words down into smaller parts (i.e., syllables or phonemes). This measures phonetic coding.

Subtest 4: Rapid picture naming. On this task, the examinee is required to name as many items pictured as possible, within a given time limit. This subtest measures naming facility.

Subtest 5: Sentence repetition. This task involves listening to sentences and repeating the words in the correct sequence. This subtest is a measure of listening ability and memory span.

Subtest 6: Understanding directions. In this task, the examinee must point to aspects of a picture in response to oral directions. This provides a measure of language development and listening ability.

Subtest 7: Sound blending. In this task, the examinee is asked to combine orally presented sounds in order to form a whole word. This subtest is a measure of phonetic coding and synthesis.

Subtest 8: Retrieval fluency. On this task, the examinee is given a category and must name as many items within that category as possible within a time limit. This provides a measure of ideational fluency.

Subtest 9: Sound awareness. This task involves rhyming, sound deletion, sound substitution, and sound reversal. This provides a measure of phonetic coding, analysis, and synthesis.

Subtest 10: Vocabulario Sobre Dibujos. This is the Spanish version of *picture vocabulary*.

Subtest 11: Comprensión Oral. This is the Spanish version of *oral comprehension*.

Subtest 12: Comprensión de Indicaciones. This is the Spanish version of *understanding directions*.

The WJ-OL subtests are clustered within four oral language subdomains: (1) oral expression (which consists of the *picture vocabulary* and *sentence repetition* subtests), (2) listening comprehension (which consists of the *oral comprehension* and *listening comprehension* subtests), (3) phonetic coding (which consists of the *segmentation* and *sound blending* subtests), and (4) speed of lexical access (which consists of the *rapid picture naming* and *retrieval fluency* subtests).

Historical Background

The WJ-IV battery was developed based upon contemporary revisions to the Cattell-Horn-Carroll (CHC) theory of cognitive ability (Schneider and McGrew 2012). This theory blends elements of Cattell and Horn's Gf-Gc theory (Cattell 1941; Horn 1965) with Carroll's Three-Stratum theory.

Cattell and Horn's Gf-Gc Theory

Cattell (1941, 1943, 1950) described two broad cognitive abilities that make up general intelligence (G): fluid intelligence (Gf) and crystallized intelligence (Gc). Gf refers to the ability to reason and problem solve, including "drawing inferences, concept formation, classification, generating and testing hypotheses, identifying relations, comprehending implications, problem solving, extrapolating, and transforming information," as well as deductive and inductive reasoning (McGrew 2009). Gc refers to the knowledge that is acquired through acculturation, including knowledge of language, factual information, and cultural concepts. Horn (1965) later expanded the theory to include four additional specific cognitive abilities: Short-term memory (Gsm), long-term retrieval (Glr), processing speed (Gs), and visual-spatial thinking (Gv). Gsm refers to the ability to immediately hold information in one's consciousness, such that the information quickly

decays if one does not transfer this information to other memory systems. Glr refers to the ability to store information in long-term memory, thus making it available for later retrieval. Gs refers to the speed at which an individual is able to perform simple cognitive tasks. Gv refers to the individual's ability to perform visual, perceptual, or spatial cognitive tasks. Horn and Stankov (1982) added the construct of auditory processing (Ga), which refers to the ability to perceive, organize, synthesize, and interpret sound. In 1989, the Woodcock-Johnson Revised battery (WJ-R; Woodcock and Johnson 1989) was published based on the above seven cognitive factors. Following its publication, Horn (1988, 1989) described the additional construct of quantitative ability (Gq), which refers to the individual's store of mathematical or numerical knowledge, acquired through education. In 1998, Woodcock expanded the theory to include the construct of reading/writing ability (Grw), which includes abilities for reading decoding, spelling, reading comprehension, and written narrative construction. Lastly, Schneider and McGrew (2012) modified the existing theoretical constructs to support recent findings within the neuroscience literature. This included replacing Gsm with short-term working memory (Gwm) to account for attentional control and the manipulation of information, expanding the Glr construct to include measures of lexical naming, and integrating sound memory within the operationalization of Ga.

Carroll's Three-Stratum Theory

Carroll (1993) conducted a factor analysis of 461 psychometric data sets, including some data taken from the norming sample of the original *WJ Psycho-Educational Battery*. Based on this analysis, Carroll identified three levels of cognitive ability. Stratum I refers to the narrowest of cognitive abilities, in which Carroll identified 69 different narrow abilities. Stratum II refers to broad categories of cognitive ability, in which Carroll identified fluid intelligence, crystallized intelligence, general memory and learning, broad visual perception, broad auditory perception, broad retrieval ability, broad

cognitive speediness, and processing speed. Finally, Stratum III refers to general intelligence or the broadest factor describing a person's overall cognitive ability.

As McGrew (2009) notes, the commonalities between these domains and those included in Cattell and Horn's theory led theorists to combine them into a single theory of intelligence (CHC Theory). The structure of the WJ-IV assessment battery is based upon this combined theory, in that the subtests (which measure narrow, Stratum I abilities) are grouped into factors (Stratum II), which combine to generate a measure of general intelligence (Stratum III). Stratum II abilities assessed by the battery include comprehension/knowledge (Gc), long-term retrieval (Glr), visual processing (Gv), auditory processing (Ga), fluid reasoning (Gf), processing speed (Gs), short-term working memory (Gsm), reading-writing (Grw), quantitative knowledge (Gq), and domain-specific knowledge. The WJ-IV Cog battery includes two measures of g: general intellectual ability (GIA) or brief intellectual ability (BIA), the latter being based on just three subtests. Likewise, the WJ-IV Ach and OL batteries include an overall achievement and language score.

Psychometric Data

The WJ-IV Cog, Ach, and OL batteries are co-normed, meaning that the three batteries were normed using the same normative sample. The normative sample consists of 7416 subjects, drawn from 47 "geographically diverse" communities in the United States. The norms provide a preschool sample (children ages 2–5 who were not yet enrolled in kindergarten), a kindergarten–grade 12 sample, an undergraduate and graduate student sample, and an adult sample. The norms cover ages 24 months through over 90 years. Sampling controlled for geographical region, community size, sex, country of birth, race, Hispanic status, type of school or university attended, parent education, educational level achieved by adults, occupational status of adults, and type of occupation. Normative sampling was based on the 2010 census projections.

Because the WJ-IV Cog, Ach, and OL batteries are co-normed, the battery also includes discrepancy norms, which allow the examiner to determine the significance of a discrepancy found between an examinee's cognitive, achievement, and language test scores. The battery also provides for intra-cognitive, intra-achievement, and intra-language discrepancy norms, by comparing an individual's performance on one subtest to their average performance across all subtests.

Reliability

The WJ-IV Technical Manual (McGrew et al. 2014) provides extensive reliability data, including measures of standard error (as an indication of the precision of an individual's test scores), internal consistency, alternate forms (reliability ranging from 0.79 to 0.95), test-retest reliability for WJ-IV Cog standard battery (median reliability ranging from 0.86 to 0.93), test-retest reliability for WJ-IV Ach standard battery (median reliability ranging from 0.89 to 0.94), test-retest reliability for WJ-IV OL battery (median reliability ranging from 0.80 to 0.94), and test-retest reliability for speeded tests (median reliability ranging from 0.85 to 0.95).

Validity

Construct validity for the WJ-IV Cog battery was established through confirmatory factor analyses, which fit the WJ-IV subtests to the CHC factor structure. All cognitive subtests loaded on a single factor, suggesting that they were not influenced by variance unrelated to the construct of G. Further, low correlations were found between cognitive battery clusters, suggesting that the clusters measure distinct things. Results of the achievement battery analyses showed less distinction among domains.

To further assess construct validity, 1056 validity study subjects were recruited (in addition to the normative sample) to compare results of the WJ-IV battery to other tests of cognitive ability and achievement. Correlations between the GIA score and overall IQ score from a number of other cognitive tests (i.e., Wechsler Preschool and

Primary Scales of Intelligence, Wechsler Intelligence Scales for Children, Wechsler Adult Intelligence Scale, Differential Ability Scales, Kaufman Assessment Battery for Children, and Stanford Binet) generally fell within the 0.80 range. In terms of the WJ-IV Ach battery, the total achievement score was highly correlated with the total achievement score from the Wechsler Individual Achievement Test (0.90) and the overall composite from the Kaufman Test of Educational Achievement (0.91). The WJ-OL oral language domain is strongly correlated (0.60–0.80 range) with global oral language scores from the Clinical Evaluation of Language Fundamentals, Comprehensive Assessment of Spoken Language, Oral and Written Language Scales, Kaufman Assessment Battery for Children, and Wechsler Individual Achievement Test.

Clinical Uses

The WJ-IV batteries have a number of clinical uses, including identifying cognitive, academic, and language skills for the purpose of educational planning. While the cognitive and oral language batteries are useful in the diagnosis of intellectual disabilities and specific language disorders, all batteries can aid in the diagnosis of learning disorders. Because of the CHC factor structure and inclusion of intraindividual discrepancy norms, the battery is useful in identifying an individual's profile of strengths and weaknesses, which can aid in educational and treatment planning. This is particularly useful for assessing individuals with autism spectrum disorders, who often demonstrate a high degree of variability among specific areas of cognitive ability.

Word Use

Aparna Nadig

Disorders, McGill University, Montreal, QC,

Definition

In language development, word use refers to how a word is mapped to the world. For example, initially a child may produce the word “dog” to refer to all animals with four legs, or perhaps just to refer to the family pet. The mapping between word and referent shifts over time until the term is used to refer to the category conventionally associated with the word in the language community, in this case the category of dogs.

Individuals with Autism Spectrum Disorder (ASD) have been observed to use words in non-conventional ways well beyond the early stages of language development. Different types of unusual

word use have been noted: mapping a word to an aspect of the context present when it was first heard; attributing a personal, idiosyncratic meaning to a word that is conventionally used in a different way (e.g., “furnace” for “stomach”); slight modification of the sound of words so that the meaning remains comprehensible (e.g., “cuts and bluesers” for “cuts and bruises”); and overly precise or pedantic use of words for the situation (e.g., “vignette” for “cartoon”).

Whereas nonconventional word use declines with increasing language ability in typical development and developmental disorders other than ASD, it has been found to increase along with language ability in ASD, being more prominent in highly verbal individuals.

Definition

Work placements are periods of supervised work that provide a person with the opportunity to gain practical training and experience within an organization. The duration of work placements can vary, ranging from a few days to several months, and can be paid or unpaid. This entry focuses on work placements for high school students with autism spectrum disorder (ASD), presenting current knowledge on how work placements can support their transition into employment.

Historical Background

The transition to adult life for youth with ASD is a phase full of uncertainty, anxiety, and challenges (Schall et al. 2012). Outcomes for adults with ASD are poor and, in many cases, are poorer than those with other disabilities. Participating less in postsecondary education and employment than the general population (Shattuck et al. 2012), youth with ASD are two times less likely to obtain a certificate, diploma, or bachelor's degree or higher than people with other disabilities (Australian Bureau of Statistics 2017). Adults with ASD are employed at a rate 50–75% lower than those without ASD or with other disabilities (International Society for Autism Research 2018).

Employment is an important major life area of adulthood, providing a key mechanism promoting social inclusion, enabling financial independence, and fostering well-being and quality of life (Lee and Carter 2012). Despite individuals with ASD commonly possessing specific skills and abilities beneficial in employment (Jones et al. 2018; Lee et al. 2019) including attention to detail, technical abilities, visual perception, and a preference for repetitive or monotonous tasks (Bölte et al. 2019), the core challenges of ASD (Strickland et al. 2013) and the lack of support after exiting high school for many pose a barrier to finding successful employment (Wehman et al. 2012).

Interventions seeking to strengthen adaptive behaviors while reducing the maladaptive behaviors associated with ASD among high-school-aged students and young adults demonstrate limited effectiveness in improving competitive employment outcomes for youth with ASD (Wehman et al. 2017). Conversely, emerging research suggests that work placement programs during high school may improve competitive employment outcomes for youth with ASD (Wehman et al. 2017). Evidence is emerging that for youth with ASD actually experiencing work, by spending time in real work environments such as in work placements, is likely one of the most promising strategies in reducing the underemployment and unemployment experienced by youth with ASD. Developing manualized and replicable approaches, which build pathways to employment for youth with ASD by mapping strengths and interests to employment opportunities, build skills through work placements, and culminate in community-based competitive employment, is an area of priority for both service providers and autism researchers (Wehman et al. 2017).

Current Knowledge

An emerging body of evidence points toward the importance of preparing youth with ASD for employment. Work experience in high school predicts later employment success (Whittenburg et al. 2018), while those with access to transition

programs and support services are more likely to gain employment (Hendricks 2010). Practical work experience opportunities can help youth with ASD in recognizing their career-related strengths and interests, identifying their goals, improving their employment-related skills, and expanding their knowledge of occupational options (Lee et al. 2019). These experiences support pathway planning for postsecondary education and careers and build work readiness (Lee et al. 2019). A recent Australian-based study exploring work experience in Information and Communication Technology (ICT)-related fields for adolescents with ASD highlighted that even short-term work placements ranging between 5 and 10 days can enable these adolescents to gain practical insight into the real workplaces, explore and extend their interests, increase their confidence, and plan for the future (Lee et al. 2019).

While research is still emerging, there is evidence to suggest that work placements have a long-term and positive impact on employment outcomes (Wehman et al. 2017). Wehman et al. (2017) conducted a randomized control trial evaluation of the “Project SEARCH Plus ASD Supports program” in the United States. Youth with ASD assigned to the Project SEARCH group, or the intervention group, participated in a 9-month internship program during their last year of high school, and in comparison with those receiving usual high school education services (the control group), those in the intervention group demonstrated higher rates of community-based employment and worked more hours per week at graduation and at 3-month and 12-month follow-up. The majority of Project SEARCH participants were still employed 12 months after the intervention, providing high-level evidence that community-based work placement is beneficial in promoting the employment outcomes of youth with ASD (Wehman et al. 2017).

Several important factors contribute to the success of work placement for youth with ASD including job match, job coach support, and environmental factors. Similar to their typically developing peers, young people with ASD are motivated by the nature of the job (Beyer et al.

2016; Scott et al. 2015), with a good job match influencing their work performance in relation to initiative, productivity, and interest in the task (Beyer et al. 2016). Harnessing the strengths and interests of adolescents with ASD in work placements (Lee et al. 2019), by crafting work experience to ensure assigned tasks capture and align with their interests and aspirations and that their needs are met (Wehman et al. 2017), is key in ensuring successful short-term work placements. Profiling the skills of youth with ASD prior to commencing work placement through comprehensive skills assessment enables adolescents and employers to develop placements likely to be the most beneficial in promoting their skill development and motivation (Beyer et al. 2016). Matching work tasks to the skills and abilities of youth with ASD enables them to see their potential and abilities as valuable future employees, strengthening their skills and knowledge in areas of interest, assisting them in planning for future education and career pathways (Lee et al. 2019).

Assistant positions in retail, catering (in the kitchen and in service roles), horticulture, child care, information technology (IT), cleaning, warehousing, mechanics, leisure and sport, and hair and beauty provide many work placement opportunities for youth with ASD (Beyer et al. 2016). Job coaching is an important strategy in promoting success in work placements for youth with ASD, particularly those with developmental or intellectual disability. Job coaches are allocated based on the needs of youth with ASD and take a person-centered approach to mapping an individual's career pathway, preparing them for employment, and supporting them in overcoming barriers. A study in the United Kingdom with youth with ASD aged 15–21 years with severe and complex needs found that a job coach improved their acquisition of work skills, including communicating with others, concentrating on tasks, remembering and following instructions, working without support, undertaking a range of tasks, and taking initiative (Beyer et al. 2016). Collectively, these findings suggest that job coach support combined with work placement experiences may be helpful in assisting youth with ASD in preparing for employment.

In addition to job coaching, behavioral supports are beneficial in supporting youth with ASD who experience difficulty understanding workplace expectations. Positive behavior support programs can promote an understanding of appropriate workplace behaviors, such as maintaining personal space and using appropriate language (Wehman et al. 2012). In the “Project SEARCH Plus ASD Supports program” evaluation conducted in the United States, on-site job coaches and combined with behavioral supports delivered promising results in helping students with ASD to gain and maintain community-based competitive employment (Wehman et al. 2017).

Targeting environmental factors is a key consideration for work placement interventions. Environmental factors extend beyond the physical environment and layout of workspaces to include the commitment, attitudes, and understanding of work colleagues and management and their knowledge of the needs of people with ASD (Lee et al. 2019). The social model of disability suggests that disability can often be minimized or avoided through an accommodating environment (physical, cognitive, or emotional) and the provision of assistive tools (den Houting 2019). Leadership from senior staff and management in promoting an autism-friendly work environment and a balanced understanding of ASD, which includes recognizing the strengths and challenges of autistic individuals, is crucial in enabling successful work placement experiences (Bölte et al. 2019). Preparing workplaces prior to placing youth with ASD, through education aimed at promoting both an understanding of ASD and appropriate communication strategies, can help to ensure positive experiences. Qualitative evaluation of a short-term work placement by Lee et al. (2019) found that providing autism education to supervisors and staff was a key factor in understanding the strengths and challenges of youth with ASD enabling job matching and ultimately underpinned the program.

Other contextual factors influencing the success of transition to employment for people with ASD include the support of family members and personal factors such as independence and social

skills (Beyer et al. 2016). Family members may at times be protective of their young people with ASD, inadvertently limiting their exposure to new experiences (Beyer et al. 2016). Service providers aiming to support youth with ASD and their families through the transition process should be well informed and clear in the messages they convey to families in regard to the available employment options (Beyer et al. 2016). Programs aimed at improving independence and social skills, such as peer mentoring, can work toward minimizing personal barriers to employment (Carter et al. 2012; Olsson et al. 2015).

Work placements for youth with ASD are not possible without the support from businesses and organizations, highlighting the importance of autism service providers partnering with industry. Whittenburg et al. (2018) outlined a four-step guide for transition specialists aiming to identify and engage with local business partners in developing integrated work placements for young people with ASD: (1) identifying potential business partners and targeting businesses based on student strengths, preferences, and skills; (2) engaging in introductory meetings with the goal of clarifying roles and responsibilities of both work experience students and their employers; (3) engaging in productive conversations with employers, learning about their business, and scoping how the partnership could meet specific business needs; and (4) enabling opportunities for youth with ASD and employers to connect through job trials, a tour of the business, or inviting a business representative to school events. Placing youth with ASD with employers and organizations is potentially beneficial to business, given youth with ASD often take new perspectives and have diverse ideas (Lee et al. 2019), can positively impact the attitudes of staff and customers, and reflect positively on the company image (Beyer et al. 2016).

Future Directions

Work placements improve the employment outcomes of youth with ASD, providing opportunities for developing and practicing essential work

and social skills important in employment. Work placements provide the opportunity for employers to observe the skills and abilities and recognize the value of employees with ASD. Work placement opportunities increase the chances of youth with ASD in successfully gaining and maintaining employment after graduation, despite the challenges and impairments associated with a diagnosis of ASD (Schall et al. 2015). However, there is a need for more research aiming to develop work placement frameworks, replicable across industries. Future research should also consider the costs and intensity of intervention required to achieve meaningful employment outcomes (Wehman et al. 2017). Fostering links between service providers and high schools, with the shared goal of bridging the gap between school and employment, has the potential to improve employment outcomes for these young people. While work placements show promise as a means of improving employment outcomes for youth with ASD, the success of such approaches depends on cooperation between education and service providers and industry.

Workforce Innovations Opportunity Act

Definition

On July 22, 2014, President Barack Obama signed The Workforce Innovation Opportunity Act

(H.R. 803) into law. This reauthorized the Workforce Innovation Act of 1998 for an additional 6 years from 2015–2020. “WIOA opens the door to states’ greater use of sector partnerships and career pathway models and includes higher levels of accountability and outcome data reporting” (National Skills Coalition 2016). This is the most significant piece of legislation for people with disabilities since the passage of the Americans with Disabilities Act of 1990. A central focus of this piece of legislation is upon transition aged youth. It has reallocated 15% of State Offices of Vocational Rehabilitative Services funding to be spent on this age group. The goal of this legislation is to obtain competitive integrated employment for job seekers. State agencies can no longer make direct referrals to sheltered workshops placing individuals with disabilities in sub-minimum wage jobs (34 CFR Parts 361, 363, 397). In the event such a placement is necessary the law requires outside periodic evaluations (Butz 2016). Under WIOA, the performance benchmarks for state offices of Vocational Rehabilitative (VR) Services have also changed. No longer will a consumer’s case be dropped from the VR caseload after the individual has worked 90 days. This practice led to the agencies measuring their success by the number of cases they closed. Now the emphasis is upon longevity in a career and the generation of a living wage. It also calls for better integration of services for consumers through the creation of one-stop centers where all of an individual’s needs related to employment can be addressed. WIOA specifically calls for “. . . transition services for students with disabilities that facilitate the transition from school to post-secondary life, such as achievement of an employment outcome in competitive integrated employment, or pre-employment transition services. . . (H.R. 803-233).”

The Secretary of Education proposed changes to Vocational Rehabilitative Services and State Supported Employment Services program (Supported Employment program) (34 CFR Part 363). According to the proposed changes “Giving workers with disabilities the supports and the opportunity to acquire the skills that they need to pursue in-demand jobs and careers is critical to

growing our economy, ensuring that everyone who works hard is rewarded, and building a strong middle class. To help achieve this priority for individuals with disabilities, the Rehabilitation Act of 1973, as amended by WIOA, seeks to empower individuals with disabilities to maximize employment, economic self-sufficiency, independence, and inclusion and integration into society” (34 CFR Parts 361, 363, and 397. P. 5). WIOA seeks to streamline services and coordinate both services and funding on federal, state, and local levels, making it easier for job seekers with disabilities to connect with employers. The Act also places a heightened emphasis on competitive integrative employment for people with disabilities (34 CFR Parts 361, 363, and 397. P. 8) regardless of the extent of the disability. “The term competitive integrated employment means work that is performed on a full –time or part-time basis (including self-employment)- (A) for which an individual is compensated at a rate that shall not be less than the higher of the rate specified in the Fair Labor Standards Act of 1938 or the rate specified in the applicable state or local minimum wage law. . .” (H.R. 803-209).

Aside from placing an emphasis on streamlining federal, state and local services, and placing individuals with disabilities in competitive employment, a third emphasis is on students with a disability and youth with a disability. The law provides for a continuum of services. There are new requirements to provide pre-employment transition services as well as transition services to students and youth with a disability. It is worth noting that pre-employment transition services can now be funded, such services were excluded in previous versions of the act. Students and youth on the autism spectrum need training in many of the soft skills critical to obtaining and keeping employment (e.g., interview skills, dressing appropriately for the environment, independent living skills, travel training, appropriate peer and supervisor communications, etc.). Training and education for these activities were not previously funded. The changes in the Act are designed to maximize the potential of these individuals to transition to postsecondary education and employment.

WIOA has adopted the definition of an “Individual with a Disability” as identified under section 3 of the Americans with Disabilities Act (42 U.S.C. 12102) (H.R. 803-209). The law also adopted language from the Individuals with Disabilities Education Act (20 U.S.C. 1414(d)(1) (A) (i) (VIII) in describing students with a disability who were eligible for the new emphasis on pre-employment training. Essentially students who were eligible for special education services and received those services qualify for this support. The law broadens the definition to include individuals who qualified as individuals with a disability under Section 504 (H.R. 803-212). The age range with which Vocational Rehabilitative Services can work with youth with disabilities has been extended under WIOA when compared to IDEA. Under WIOA, “The term ‘youth with a disability’ means an individual with a disability who – (i) is not younger than 14 years of age; and (ii) is not older than 24 years of age” (H.R. 803-213).

Institutions of Higher Education (IHE) can, in fact, provide pre-employment and employment transition services to individuals with disabilities under WIOA. The statute specifies performance measures for the state agencies which include measuring the percentage of program participants who obtained a secondary diploma or its equivalent, or enrolled in an education or training program leading to a recognized postsecondary credential. A “recognized postsecondary credential” is defined in WIOA sec.3(52) as “a credential consisting of an industry-recognized certificate or certification, a certificate of completion of an apprenticeship, a license recognized by the State involved or the Federal Government or an associate or baccalaureate degree” (34 Code of Federal Regulations (CFR) Parts 361 and 463. P. 55983). Furthermore, the Act’s definition of one-stop delivery systems and entities that can serve as one-stop partners indicates this reality. “The one-stop delivery system brings together workforce development, educational, and human resource services in a seamless customer-focused service delivery network that enhances access to the programs’ services and improves long-term employment outcomes for individuals receiving

assistance” (34 Code of Federal Regulations (CFR) Parts 361 and 463. P. 56009). Institutions of Higher Education are explicitly cited under the definition of one-stop operators under WIOA: “One-stop operators may be a single entity (public, private, or nonprofit) or consortium of entities. . .the types of entities that may be a one-stop entity include: (1) An institution of higher education. . .” (34 Code of Federal Regulations (CFR) Parts 361 and 463. P. 56014).

The Workforce Innovation Opportunity Act mandates required activities that fall under the provision of pre-employment transition services. These include “(1) job exploration counseling; (2) work based learning experiences, which may include in-school or after school activities, or experience outside the traditional settings (including internships), that is provided in an integrated environment to the maximum extent possible; (3) counseling or opportunities for enrollment in comprehensive transition or post-secondary educational programs at institutions of higher education; (4) workplace readiness training to develop social skills and independent living; and (instruction in self-advocacy, which may include peer mentoring” (H.R. 803-234).

WIOA identifies six primary indicators of performance for adult and dislocated worker programs, AEFLA programs, and the VR programs. These are (1) the percentage of participants who are in unsubsidized employment during the second quarter after exit from the program; (2) the percentage of participants who are in unsubsidized employment during the fourth quarter after exit from the program; (3) median earnings of participants in unsubsidized employment during these two time periods; (4) the percentage of those participants enrolled in education or a training program who attained a recognized postsecondary credential or a secondary school diploma; (5) the percentage of participants who, during the a program year, are in an education or training program that leads to a recognized postsecondary credential or employment who are achieving measurable skill gains; and (6) effectiveness in serving employers (34 Code of Federal Regulations (CFR) Parts 361 and 463. P. 56028).

Historical Background

The most immediate precursors to the Workforce Innovation Opportunity Act were the Job Training and Partnership Act (JTPA) of 1982 and the Workforce Investment Act (WIA) of 1998.

The Workforce Investment Act, and its later reauthorization (and significant expansion) with the Workforce Innovation Opportunities Act, attempts to integrate the intentions of nearly a century of legislation addressing the need for independence and community-based work opportunities for individuals not participating in the workforce for either economic reasons or due to the challenges of a disability. The components of WIOA that are most germane to young adults and adults with a diagnosis of autism represent an integration of three distinct legislative agendas.

Some legislations, such as the Wagner-Peyser Act (1933), the Manpower Development Training Act (1962), the Comprehensive Employment and Training Act (1973), and the Job Training and Partnership Act (1982), focused primarily on assisting individuals not participating in the workforce for economic and educational reasons not necessarily related to any disabilities. All of these acts provide vocational support for individuals with a disability, but it was not the precise focus of any of the acts. The Rehabilitation Act (1973) and the American's with Disabilities Act (1992) more specifically address the provision of supports for individuals with disabilities seeking to find work. The Individuals with Disabilities Education Improvement Act (2004) and certain provisions of the Higher Education Opportunity Act (2008) address the importance of preparing young adults with a disability to transition from an educational setting to independent living and work. The WIOA is the most comprehensive attempt by Congress to combine the initiatives and the agendas of these three distinct strains of legislation in one act.

One of the first pieces of legislation advocated for by President Franklin D. Roosevelt was the Wagner-Peyser Act, which created a national network of public employment services offices that remains in effect to this day. There had been prior, less successful, attempts at creating similar

national networks. "The [national employment network] continues to serve as the foundation for the national One-Stop delivery system established by the workforce Investment Act of 1998" (O'Leary and Eberts 2008, p. 1). A key component of the WIOA reauthorization of the Workforce Investment Act is the One-Stop aspect of accessibility for those seeking assistance.

Current Knowledge

There are few empirically based research studies on the employment of individuals on the autism spectrum. We can only glean information from studies that measure the effectiveness of an intervention or surveys that examine employment with individuals with disabilities in general. Wehman et al. (2013) found that students on the autism spectrum who were involved in a randomized clinical trial of job training had an 87.5% employment rate post-study. This was statistically and clinically significant. The control group, referred to as the business as usual group (i.e., students working with their high schools and state office of Vocational Rehabilitative Services), had only a 6.25% employment rate. Moore and Schelling (2015) did not look specifically at the autism population. However, they did examine the population of students with an intellectual disability which includes some individuals, but not all individuals on the autism spectrum. Their research indicated that 9 out of 10 students with an intellectual disability who graduated from a post-secondary program were employed with 2 years of the study. They compared their data to the findings of the National Longitudinal Transition Study 2 where only about half of the graduates of high school with an intellectual disability had been employed in the last 2 years. Anecdotally, there are some reports of the unemployment rate being as high as 90% in the autism population. This does not include a significant number of higher functioning individuals on the spectrum who are underemployed. Interestingly, Diamant (2015) found that neither IQ nor academic ability were better predictors of employment and independent living for people on the autism spectrum

than their ability to successfully and consistently complete activities of daily living (ADLs).

Future Directions

For those transition aged youth considering attending a college-based transition program paying for a program of this nature can be a major obstacle. Although WIOA will allow state offices of Vocational Rehabilitative (VR) services to pay for these programs, it will only pay for a fraction of the cost. Typically, VR will pay for the tuition for the courses at in-state public university rates. This often will not cover the room and board expenses for the student to reside on campus. Should the student on the autism spectrum decide to go out of state or go to a private university, the cost differential can be substantial. Legislators need to align the Higher Education Opportunity Act of 2008 with future amendments and reauthorizations of WIOA.

A critical component to fostering a student on the autism spectrum's ability to find and maintain employment includes learning independent living skills. Under HEOA colleges were able to create Comprehensive Transition and Post-Secondary (CTP) programs that were approved by the US Department of Education. This allowed students with ID or DD (including those with autism) to enroll in CTPs where there was a curriculum with specialized courses to address the nature of their disabilities (including independent living skills) and to receive a specific advising system. However, at least 51% of their time in the program needs to be with nondisabled peers. Often this is accomplished not only through academic course work, but also in internship placements and on-campus living. By better aligning WIOA with HEOA, students who opt to attend a private or out of state college with a US DOE approved CTP could be eligible for not only monies from WIOA that were disbursed through state offices of VR, but also these students would be eligible for Federal Student Aid under Title IV of HEOA. The grants under Title IV include Pell Grants, Federal Supplemental Education Opportunity Grants (FSEOG), and Student Work Study monies.

These grants do not need to be repaid and would help defray some of the room and board costs not covered by WIOA. Unfortunately, students with autism who are enrolled in a US DOE approved CTP are not eligible for both subsidized and unsubsidized federal student loans under HEOA. By aligning these two pieces of legislation and by lifting the provision against student loan disbursement for students in CTPs, more students on the autism spectrum could attend college-based Comprehensive Transition Programs, practice living independently, and learn independent living skills that would help them keep and maintain employment.

Clearly, future directions will require more research not only into the effects of WIOA on length of employment and wages, but also on the effects of many of its provisions including the provision of pre-employment training, peer mentoring, and one-stop centers for employment services. Research into disability-specific outcomes including autism will be paramount.

Wraparound Services

Paul K. Cavanagh
 Vocational Independence Program, New York
 Institute of Technology, Central Islip, NY, USA

Definition

Wraparound services is a phrase used to describe a comprehensive set of services for an individual with a disability, and/or their family, that addresses all of their educational, vocational, and independent living needs across all parts of their day. Such services may come from a single service provider or from several service providers working in collaboration with one another. Either way, wraparound services usually involves the use of a single service coordinator.

It is reported that the term was first coined by Dr. Lenore B. Behar in an article, “A state model for child mental health services: The North Carolina experience,” published in a 1986 issue of *Children Today*. In that article, she describes

wraparound services as a way to “surround multi-problem youngsters and families with services rather than with institutional walls, and to customize these services to the individual needs and strengths of the child and family” (LenoreBehar.com). The origins of the term specifically relate to services to children and young adults with a mental health diagnosis. Over time, the term has been adopted in various forms by most human service systems serving children and adults, including those systems serving individuals with a developmental disability. A wraparound, or continuum of care, approach to service delivery for individuals with a diagnosis of autism has been identified since the earliest days of the recognition of the syndrome. However, the word “wraparound” or the terms “wraparound process” or “wraparound services” in terms of services to individuals with a developmental disability are usually used as a descriptive term elaborating on a particular therapeutic approach. Examples of these would be applied behavior analysis, person-centered planning, or family-centered care.

Historical Background

The term “wraparound services” has its origins in services to children and youth with a mental health diagnosis in response to a perceived fragmented and disjointed service delivery system. Even in these early uses, the broken service delivery system in question overlapped with the service systems for youth with developmental disabilities as well as the juvenile justice system. Over time, the term has come to be a generic term used in multiple service delivery systems serving youth in need describing a comprehensive set of services for an individual and/or their family that addresses all of their educational, vocational, and independent living needs across all parts of their day.

Origins of the Wraparound Process

In the early 1980s, North Carolina’s Division of Mental Health, Developmental Disabilities, and

Substance Abuse Services responded to a lawsuit, known as the “Willie M.” lawsuit, on behalf of children diagnosed with severe emotional disabilities. The state office used the consent agreement as a means of developing “a comprehensive continuum of community-based care for high-risk and hard-to-manage children and adolescents” (p. 118, Jenson and Fraser 2005). In 1986 Dr. Lenore Behar, then the Chief of Child Mental Health Services for the state of North Carolina, coined the term “wraparound” in an article (Behar 1986) describing the service system for youth with a mental health diagnosis that North Carolina had developed in response to the Willie M. litigation. At that time, she described wraparound services as a way to “surround multi-problem youngsters and families with services rather than with institutional walls, and to customize these services to the individual needs and strengths of the child and family” (LenoreBehar.com/wraparound, n.d.).

Beginning in the early 1970s, the Kaleidoscope program in Chicago, led by Executive Director Karl Dennis, began to develop a community-based, family-centered approach to providing services to children with severe emotional disabilities who had been institutionalized across the country. While the Kaleidoscope model was not initially characterized as wraparound services, it is later identified as being consistent with the philosophies of the wraparound process and one for the earliest examples of the application of wraparound approach. The Kaleidoscope model envisions wraparound process as having five essential features: development of a service plan by an interdisciplinary team, community based, family focused, unconditional, and cost-effective. In the mid-1980s, the Kaleidoscope program provided consultation to officials in the state of Alaska in the development of a new program called the Alaska Youth Initiative. The program, lead by John VanDenBerg, was one of the earliest (along with North Carolina) statewide efforts to use a wraparound service model as a means of returning youth with complex mental health needs who had been placed out of state to community-based settings.

Federally Funded Programs and Wraparound Services

Wraparound services have been a central component of several federal mental health-related initiatives. The National Institute of Mental Health has funded a program called the Child and Adolescent Services System Program (CASSP) since the early 1980s. This program originally funded by Congress in 1984 grew out of a national study that found that two-thirds of all children with severe emotional disturbances were not receiving appropriate services. The CASSP approach, identified as consistent with the wraparound process, advocates for six core principles: child centered, family focused, community based, multisystem, culturally competent, and least restrictive/intrusive.

The Substance Abuse and Mental Health Services Administrations has given grants to communities across the country via its Comprehensive Community Mental Health Services for Children and Families program. The wraparound process has been a main component of a majority of these initiatives.

Early and Periodic Screening, Diagnosis, and Treatment (EPSDT) is a mandated Medicaid service for children and youth. While not specifically designed to support wraparound services, numerous states have used EPSDT as a means of funding community-based wraparound services for children and youth with mental health diagnoses as well as children and youth with developmental disabilities.

Wraparound-Type Services for Individuals with a Developmental Disability

A majority of the service models for individuals with a diagnosis of autism are consistent with the basic philosophies of the wraparound process as delineated by the National Wraparound Initiative (NWI). As delineated in the current knowledge section, NWI has identified ten principles of the wraparound process: family voice and choice, team based, natural supports, collaboration, community based, culturally competent, individualized, strengths based, unconditional, and outcome based. Two particular service models

for individuals with autism consistent with a majority of these principles are person-centered planning and Applied Behavior Analysis.

Person-centered planning is an approach aimed at improving the quality of services for individuals with a developmental disability mostly associated with the work of John O'Brien. In their consideration of the history of person-centered planning, Lyle O'Brien and O'Brien (2000) identify four concurrent initiatives in the early 1980s that they see as the foundations of what ultimately becomes known as person-centered planning. The Canadian National Institute on Mental Retardation was training staff and families in a process of 24-hour planning for individuals with severe disabilities. Beth Mount in Georgia was developing an approach she called Personal Futures Planning. Jack Yates in Massachusetts was developing the Program Design Sessions for individuals moving out of an institutional setting, and Wisconsin's system was identifying the capacities it would need to develop in order to deliver individualized services (p. 3). In turn, those involved in all of these initiatives were influenced by the definition of the principal of normalization as defined by Wolf Wolfensberger and L. Glenn in their book (and related training programs) *Program Analysis of Service Systems* (Pass) (1975).

Current Knowledge

Applied Behavior Analysis

As noted elsewhere in this chapter, the term "wraparound" is used both generically and increasingly in a very purposeful way to refer to a particular means of planning and service delivery ascribing to a specific set of agreed-upon principles. The generic use of the term refers to any instance of a comprehensive set of services that addresses all of a person's educational, vocational, and independent living needs across all parts of their day. The more concrete use of the term being advocated by the National Wraparound Initiative is described below.

The current best practices models of services for individuals with a diagnosis on the autism

spectrum stress team-based comprehensive approaches that span both the whole day and the whole year. There is not a lot of evidence that the majority of the treatment efforts for individuals with a diagnosis of autism are affiliated with the National Wraparound Initiative. However, it is clear that some of the national advisors for the National Wraparound Initiative are involved in services to individuals with a diagnosis of autism and other developmental disabilities. It is also clear that the most dominant approaches to providing services to individuals with a diagnosis with autism, such as applied behavior analysis and person-centered planning are focused on team-based and 24-h inclusive approaches. The main assumptions of the best practice approaches to providing services to individuals with a diagnosis of autism are consistent with a majority of the core principals of the wraparound process as delineated by the National Wraparound Initiative.

Ten Principles of the Wraparound Process as Developed by the National Wraparound Initiative

In 2003, a group of community leaders and researchers who were part of the larger practice community of wraparound services convened a national meeting to consider the necessary and sufficient components of the wraparound process. The meeting, hosted by the Research and Training Center on Family Support and Children's Mental Health, was the beginnings of what became the advisory group to the National Wraparound Initiative (NWI). The National Wraparound Initiative represents a group of "stakeholders-including families, youth, providers, researchers, trainers, administrators and others- [who] came together in a collaborative effort to better specify the wrap-around practice model, compile specific strategies and tools, and disseminate information about how to implement wraparound in a way that can achieve positive outcomes for youth and families" (National Wraparound Initiative [n.d.](#)).

A major initiative of the National Wraparound Initiative has been an online Resource Guide to Wraparound. A key component of this resource guide is a set of ten principles of wraparound developed by consensus by the advisors and

principals of the National Wraparound Initiative. These ten principles are as follow:

1. Family voice and choice: An emphasis on the primary importance of goals and perspective of the individual receiving services and their family and advocates in the development of the wraparound process. This principle stresses the importance of intentional activities to illicit and includes the perspective of the individual receiving services and their family and advocates.
2. Team based: This principal stresses the importance of collaborative effort of family members, professionals, and other stakeholders, committed to the family's well-being over an extended period of time. The choice of team members should be largely driven by the person receiving services and their family and advocates.
3. Natural Supports: To the greatest extent possible, a wraparound plan of service should utilize the natural support systems of family members, friends, neighbors, church, and community members. The plan should also include the regular support structures that exist in the community via school systems, church congregations, community centers, local government, etc.
4. Collaboration: The decision-making process in developing a wraparound plan of service should be based on a consensus approach that includes input from all team members.
5. Community based: Wraparound services should adhere to a principle of provision in the least restrictive setting possible.
6. Culturally competent: Team designation, service planning, and service delivery should demonstrate "respect for the values, preferences, beliefs, culture and identity of the child/youth and family, and their community" (Bruns et al. 2008, p.7).
7. Individualized: Wraparound services need to be uniquely developed for the individual in need and their family. The planning for services should draw upon the best empirical evidence of effective treatment and upon community and professional experience.

However, the services should not be assembled from a static list of available services.

8. Strengths based: A key in the development of a wraparound plan of service is to identify, “build on, and enhance the capabilities, knowledge, skills, and assets of the child and family, their community, and other team members” (p. 8).
9. Unconditional: The origins of the wraparound process grew out of a need to provide quality services to individuals with severe and complex behaviors. It is understood at the outset that this will be a difficult and challenging process. Inherent in the development of a wraparound plan of service is a commitment to see the process through despite setbacks and unanticipated behavior, events, or outcomes. There needs to be an unwavering commitment of the part of the team to continually adapt the plan of service until progress is made and there is consensus that a wraparound process is not longer needed.
10. Outcome based: Wraparound plans of service identify measurable outcomes and indicators of progress and success. The team measures and evaluates these measures on an ongoing basis and modifies plans accordingly (Bruns et al. 2008).

Future Directions

The future direction of wraparound services will depend upon the research community identifying more empirically based interventions specifically designed to help ameliorate the behaviors associated with autism spectrum disorders that interfere with social communication, independent living, vocational skills acquisition, and community integration.

Writing Disorders

Short Description or Definition

Writing is considered to have two basic components: the process and product of writing. Writing processes include “planning (prewriting), organizing, drafting, reflecting, revising, and editing. . . as well as forming letters and sequences of letters into words” (American Speech Language Hearing Association [ASHA] 2001), while the products of writing are the final form of the composition produced as either handwritten or word-processed text. Writing involves not only the physical process of forming letters and sequences of letters into words and using appropriate writing mechanics, such as punctuation and capitalization, then, but also consists of the planning, organizing, drafting, reflecting, revising, and editing that leads to the final product (Paul and Norbury 2012; Scott et al. 2009). Children who find writing difficult early in their education often perform poorly on academic measures as they progress through the grades (Nancollis et al. 2005). Children with speech-language disabilities, including those with ASD, are at risk for writing difficulties (Puranik et al. 2008).

Assessment

Writing can be assessed informally, using rubrics to rate the quality of various components of the writing process and product (e.g., Paul and Norbury (2012); Westby and Clauser 2005). In addition, standardized tests are available for the identification of writing disorders. These may be

administered by a speech-language pathologist, learning disability specialist, or special educator. They include, for example, the *Oral and Written Language Scales* (Carrow-Woolfolk 1996), the *Test of Adolescent and Adult Language-4* (Hammill et al. 2007), the *Test of Written Expression* (McGhee et al. 1995), the *Test of Written English* (Anderson and Thompson 1988), the *Test of Written Language-4* (Hammill and Larsen 2009), the *Woodcock Language Proficiency Battery-Revised* (Woodcock 1991), the *Writing Process Test* (Warden and Hutchinson 1992), and the *Written Language Assessment* (Grill and Kerwin 1990).

Categorization

The characteristics of writing disorders, according to Scott et al. (2009), include:

- Poor *planning, monitoring, evaluating*, and *revising* work. Children with writing difficulties have been described as having a “stream of consciousness” writing style (Graham and Harris 1999). Because of this, they demonstrate text-structure problems (with paragraph organization, transitions between paragraphs, and story plots). They often do not recognize and correct errors as they write (Roth 2000) or go back over their writing to correct errors later (Scott 2005).
- Difficulty with *writing mechanics*. Graham and Harris (1999) and MacArthur (2000) observe that children with writing difficulties struggle with spelling, capitalization, punctuation, and handwriting. In addition, they often write sentences that are shorter and simpler than those of their peers. They have fewer clauses per sentence, they overuse *and* to begin sentences, and often omit grammatical word endings, such as *-ed* (to express past tense).
- *Sparse writing*. Children who struggle with writing write less and get less practice writing (Wong 2000). Because of their language deficits, these children often have limited vocabularies and may not know the right word to

express their ideas. They may forget the main point, plan, or the structure of their text because they got stuck on the mechanical process of writing. These findings were confirmed by Scott (2005), who found that problems with thinking through and controlling the steps of writing create difficulty in both excluding unimportant material as well as including appropriate information.

- *Ineffective revision.* Children with writing difficulties tend to view revising as proofreading. Revisions are typically made at the sentence level, without considering changing content (Roth 2000).

Epidemiology

There are no precise estimates of prevalence for writing disorders, although the National Center for Learning Disabilities estimates that 5% of school-aged children have learning disorders; most who have disabilities in the area of reading will have writing disorders, as well.

Natural History, Prognostic Factors, and Outcomes

Natural History: Some children may have difficulty with the physical act of writing, the ability to form letters, as early as the preschool years. This specific deficit in handwriting is often referred to as *dysgraphia*. For most children, writing problems will be identified in 2–4th grade, when school-sponsored writing and spelling are targeted within the curriculum. These difficulties usually accompany reading problems and executive function difficulties and can persist throughout development, into adulthood. However, many adolescents and adults can develop compensatory strategies to that help them cope with their weaknesses and can find careers that allow them to use their strengths for successful adjustment.

Prognostic Factors: Children with reading disorders are at risk for writing disorders, as well.

Outcomes: Although deficits in spelling, handwriting, and composition often persist into

adulthood, many adults find ways to be successful in work and life.

Clinical Expression and Pathophysiology

No pathophysiological signs have been identified that are specific to developmental writing disorders, although adults with acquired dysgraphia are generally found to have lesions in the parieto-occipital region.

Evaluation and Differential Diagnosis

Evaluation and Differential Diagnoses: Writing disorders that are specific to letter formation and handwriting (dysgraphia) need to be distinguished for general motor weakness, spasticity, and incoordination that would affect processes other than writing, such as self-feeding and other hand skills. Since writing disorders almost always occur in conjunction with reading disorders, the two do not require differential diagnosis, but writing ability should always be evaluated in students with reading disorder.

Treatment

Intervention

Several aspects of writing may be addressed in an intervention program, including:

- *Writing mechanics.* Children who have specific difficulties with writing mechanics may demonstrate poor handwriting skills may fatigue or experience hand cramps quickly when writing, and may be “poor spellers.” If this is the case, the use of assistive technology, such as word processing, can be utilized effectively to reduce fine-motor demands of handwriting (MacArthur 2000). In addition, the spell check function in a word processing program can be helpful for a child who experiences difficulty with writing mechanics and spelling (MacArthur 2000). Working with word prediction software in intervention is also an option

for children with problems in writing mechanics. This software predicts a word to type, based on what has been written so far, reducing the stress of both word finding and spelling.

- *Planning and composing.* One effective strategy for improving writing process is *Self-Regulated Strategy Development* (SRSD; Graham et al. 2000). There are six “stages” in the SRSD: (1) develop background knowledge; (2) identify strategy, goals, and significance; (3) modeling of the strategy; (4) memorization of the strategy; (5) collaborative practice; and (6) independent practice. A variety of other strategies are described in Paul and Norbury (2012).
- *Revising.* Children with writing disorders may benefit from the use of assistive technology, such as speech synthesis software that allows the computer to read the composition aloud, while highlighting the words being spoken. The student can then use oral language skills to make revisions. Collaborating with classmates or teachers during revision may also be helpful (MacArthur 2000; Wong 2000). Students can be divided into small groups for peer revisions. Each child is instructed to provide, for example, two positive comments and two suggestions for improvement for their classmates’ compositions. The students might also ask questions about unclear or underdeveloped aspects of compositions.
- *Visual aids and graphic organizers* have also been shown to improve writing. Visual outlines in the form of flow charts and maps (“webs”) can help students organize the writing process (Hyerle 2004). These can be used as a basis for creating a more mature composition.

Additional examples of intervention approaches for writing difficulties can be found in Paul and Norbury (2012).

Writing Interventions for Individuals with Autism Spectrum Disorder

Amy Accardo and S. Jay Kuder

Definition

Writing is a means to communicate and express ideas, thoughts, feelings, and information. Writing interventions refer to effective and evidence-based instructional practices used to support individuals in developing varied elements of writing including but not limited to letter formation, handwriting, length of writing, sentence structure, and quality of writing. Writing interventions often target specific genres of writing including but not limited to descriptive writing, expository writing, narrative writing, and persuasive writing.

Historical Background

The topic of writing interventions and students with autism spectrum disorder (ASD) was not widely considered prior to the twenty-first century. Preceding the enactment of legislation in the 1970s, students with disabilities were denied access to general education. In 1973, Section 504 of the Rehabilitation Act was signed, mandating the inclusion of individuals with disabilities in all programs that receive federal funding, including public schools. In 1975 the Education for All Handicapped Children Act (P.L. 94-142) was signed mandating the rights of students with disabilities to a free and appropriate education in the least restrictive environment. Despite these mandates including students in public education, there was a prevailing assumption that most individuals with ASD would not benefit from instructional time spent on academic skills including writing, and instead the primary focus of education was to address behavioral and life skills.

In 1990, P.L. 94-142 was renamed as the Individuals with Disabilities Education Act (IDEA). IDEA was reauthorized in 1997 with an impactful amendment that required students with disabilities to participate in local and state assessments. IDEA was further reauthorized as the Individuals with Disabilities Education Improvement Act (IDEIA) in 2004, mandating students with disabilities receive academic instruction founded in scientifically based research. These mandates have brought about increased expectations for the academic performance of students with disabilities and the increasing inclusion of students with disabilities in general education classrooms. This includes access to the general education curriculum and participation in high-stakes testing for students with ASD in our public schools.

Students with ASD, however, have been found to struggle with academic performance, including in the domain of written expression, yet skill in writing is paramount to success in local and state assessments. Moreover, developing skill in functional writing as a communication tool is especially important for the subset of individuals with autism spectrum disorder (ASD) with limited

or unreliable speech. Faced with the mandates of IDEIA (2004), many teachers have found themselves unprepared to provide instruction that meets the individualized needs of students with ASD as well as prepares them to meet state standards. This established a need for high-quality writing interventions for students with ASD. Fortunately, there has been increased attention on how to enhance the academic performance of students with ASD in the area of writing.

Current Knowledge

Individuals with ASD often experience reduced success in writing, placing them at a disadvantage in communicating their thoughts, fully participating in school, or gaining employment (Pennington and Delano 2012). Specific writing difficulties include using fewer words and making more spelling errors than their neurotypical peers and having weaker overall structure in their writing (Asaro-Saddler 2014, 2016). In a study of the learning profiles of children with high-functioning autism, Mayes and Calhoun (2008) report that despite strength in visual and verbal reasoning, students with ASD have writing weaknesses, including difficulty with handwriting and with expressing thoughts on paper. Additionally, difficulty with perceptual and visual motor tasks has been found to impact functional handwriting including length, speed, and legibility of writing (Ashburner et al. 2012).

Differences in executive functioning and theory of mind (ToM) have frequently been reported to impact the writing of individuals with ASD. Executive functioning differences may result in difficulty generating, planning, and integrating ideas in writing for individuals with ASD, and as a result instructional practices aimed at supporting the planning, organization, and self-monitoring of writing emerge as essential (Delano 2007). Differences in ToM, the ability to consider the thoughts or feelings of others (Baron-Cohen et al. 1985), have been reported as impacting the ability of individuals with ASD to write persuasively (Asaro-Saddler and Bak 2014) and the quality of both narrative and expository texts

(Brown and Klein 2011). More recently, an emphasis on ToM differences as opposed to deficits has led to consideration of how ToM variations may also emerge as strengths for individuals with autism (see Atherton et al. 2019). For example, strength in imagination and attention to detail may enrich the narrative story writing of individuals with ASD.

Writing Interventions

Numerous interventions have been identified to improve the writing of individuals with ASD. Many of these writing interventions stem from practices identified as evidence-based (EBPs) for instructing students with ASD in a variety of skill areas (see Reichow et al. 2008). Such EBPs include reinforcement, task analysis, prompting, time delay, video modeling, and use of visual supports (National Professional Development Center on ASD 2014). In fact, combining multiple instructional practices to individualize writing intervention for individuals with ASD has emerged as a common practice with interventions frequently combining visual supports, such as a graphic organizer, along with positive reinforcement (Accardo et al. 2019). Reviews of the literature detail writing interventions to support individuals with ASD (see Pennington and Delano 2012; Asaro-Saddler 2014; Accardo et al. 2019). Recommended writing interventions along with examples of implementation follow.

Self-regulated strategy development. Self-regulated strategy development (SRSD) is an instructional package that includes the teaching of academic strategies for writing combined with instruction in self-regulation. Through SRSD, teachers individualize instruction and guide students to use writing strategies while also providing support for student goal setting, self-regulation, and motivation. Instruction includes six stages: (1) developing background information needed for writing; (2) discussing the purpose and benefit of the strategy to be used; (3) modeling of the strategy, often through teacher think-alouds; (4) memorizing the strategy steps, often through the use of a mnemonic (e.g., the mnemonic POW+TREE for the strategy steps: Pick an idea, Organize notes, Write, Topic sentence,

three or more Reasons, Ending, Examine); (5) supporting students in use of the strategy; and (6) independence, evidenced by student generalization of the strategy across a variety of tasks (Santangelo et al. 2008). SRSD is individualized with instruction at each stage continuing until student mastery through a criterion-based approach.

SRSD has emerged as a highly effective writing intervention for individuals with learning disabilities as well as individuals with ASD. In a study of the use of SRSD with three elementary-age students with ASD, students were taught to use the POW+ Tree strategy and the WWW, What-2, and How-2 writing strategy, given a choice of writing tasks, a motivational “rocket” chart, and visual supports. All of the students increased the number of story elements used, the holistic quality, and the number of words when writing stories (Asaro-Saddler 2014). Similarly, in a study of SRSD which included choice of writing tasks, self-regulation charts, cue cards, and a computer graphic organizer program, all of the students aged 18–20 increased the quality of argument-driven writing and writing duration (using the strategy DATE + SCORES) and quality appeared to generalize to prompts in a college writing course (Jackson et al. 2018). In a review of the research literature on the effectiveness of SRSD with individual with ASD, Asaro-Saddler (2016) concluded that most students with ASD participating in SRSD instruction increased both the quality and quantity of their writing. In addition, students increased their planning time and their use of self-regulatory strategies. Since many students with ASD are reported to have difficulty with executive functioning tasks such as planning, organizing, and self-monitoring, the SRSD method may help these students to organize their thoughts and to check the quality of their writing.

Graphic organizers. The use of visual information during instruction, such as through graphic organizers and pictorial representations, allows students to process information faster and easier. Graphic organizers provide a visual representation of information to enhance learning. As a component of the SRSD method, graphic organizers have been shown to be part of an effective

instructional package for enhancing the writing skills of individuals with ASD. For example, Bishop et al. (2015) implemented a graphic organizer package to improve the persuasive writing of three middle school students with ASD. The graphic organizer had spaces for planning – a brainstorming box, three boxes for reasons, a counter-argument box, an introduction box, and a conclusion box. After training with the graphic organizer, all three students improved on all three of the outcome measures – correct writing sequences (defined as “two adjacent writing units that are correct within the context of what is written”), total words written, and a rubric score.

Behavioral Principles

Prompting. Instructional methods derived from applied behavior analysis (ABA) are also recommended to enhance the writing of individuals with ASD (see ► “Progressive Applied Behavior Analysis”), often in combination with other instructional methods. One such method is prompting. For example, response prompting was combined with sentence frames to improve the sentence writing of 7–12-year-old students with moderate intellectual disability and ASD (Pennington et al. 2018). A sentence frame is a scripted portion of a sentence – for example, “I want _____” – that can be completed by using a targeted written response such as “I want the candy.” During instruction, the teacher presented the student with a preferred item and the sentence frame and prompted the student to respond by saying “Write a sentence to tell me what you want.” If the student failed to respond within 10 s, the teacher prompted the student using a predetermined prompt hierarchy. If the student responded correcting the teacher provided either p-raise or a tangible reinforcer. Using these procedures, each of the students produced three types of sentences and maintained their responding following the intervention.

Task Analysis. Similarly, a task analysis approach can be used to enhance the writing of individuals with ASD. For example, Lee et al. (2016) used a task analysis approach to identify the steps needed to teach three skills: identification of key ideas in a paragraph, identifying

supporting details and recording information on a graphic organizer, and composing informational text. Two students with significant intellectual disabilities, one of whom was identified as autistic, were instructed on writing skills using the task analyses as the framework for the instruction. In addition, during instruction teachers used a graphic organizer that consisted of written prompts for each of the three target skills and utilized a least intrusive prompt approach if the student did not respond during the lesson. Following instruction, both of the students made significant improvements on all three skills.

Reinforcement. Reinforcement of behavior is another ABA method that has frequently been used to teach writing skills. In their review of the research on writing interventions for students with ASD, Pennington and Delano (2012) identified 11 studies in which reinforcement was used. A number of different methods were identified, including the delivery of tokens, a computer-delivered auditory fanfare for correct responding, and a reinforcing video clip. Since student preferences can vary widely, it is important to assess individual student response to reinforcers before choosing a method to use to reinforce student responses to writing tasks.

Assistive Technologies

Computer-aided instruction. Assistive technologies, including computer-aided instruction, voice output communication aids (VOCAs), multimedia presentations, and video modeling, have been successfully used to improve the writing of individuals with ASD. Using computer-aided instruction (CAI), Stromer et al. (1996) developed software to teach a student with intellectual disability and ASD to improve spelling. The student was presented with a sample word on the computer screen which, when touched, disappeared and was replaced by a set of letters. The student could then select the correct letters to spell the target word. When the student responded correctly, the computer lit up with a flashing display, and the student received a token that could be exchanged for a preferred item. The student with ASD was able to successfully spell words using this method, and

spelling improvement was found to generalize to other tasks.

Additional studies provide example of how CAI, used in combination with other instructional practices, can be used to teach writing skills to individuals with ASD. Pennington et al. (2014) combined simultaneous prompting, an errorless teaching procedure involving the delivery of a controlling prompt immediately following a discriminative stimulus, with CAI to teach story writing to five students with autism (see Pennington et al. 2010, 2014). Story templates were created using commercially available software, and the participants were prompted to create a story using words and pictures on the story template. In both studies the researchers found that the combination of simultaneous prompting with computer-aided instruction improved the ability of the students to construct stories. Additionally, students showed evidence of generalizing their story construction skills through increased verbal responses.

Voice output communication aids. Assistive technology includes the use of voice output communication aids to support the written expression of individuals with ASD. Two studies by Schlosser and colleagues combined the use of a voice output communication aid (Lightwriter 35) with a copy-cover-compare method to teach spelling to students with ASD (see Schlosser et al. 1998; Schlosser and Blischak 2004). In the first study, a student with ASD significantly increased correct spelling of words and maintained the improvement after the intervention was completed. In the follow-up study in 2004, the investigators used a similar copy-cover-compare method to teach spelling combined with the use of three different forms of feedback – speech, print, and speech + print – with four students with ASD. Results were similar to that found in the earlier study in that all of the participants increased their correct spelling. However, only two of the four students were able to generalize their skills to new words. There was no single type of feedback that was superior, but the results suggest that some individuals with ASD may respond better to print feedback, while others may prefer feedback in the form of speech.

Video modeling. Video modeling has been found to be an evidence-based practice for improving the learning and behavior of individuals with ASD (Wong et al. 2015). When applied to writing instruction, video modeling has been found to enhance essay writing (Delano 2007) and spelling (Kinney et al. 2003; Kagohara et al. 2012). For example, SRSD was delivered via video self-modeling to three young adults with Asperger syndrome (Delano 2007). The young adults participated in making two videos of themselves modeling the use of a strategy – one to increase the number of words written and the other to enhance essay writing. The students watched the video at the beginning of each intervention session. Following the interventions, all of the students increased the number of words used in their essay writing and increased the number of functional elements (e.g., premises, reasons, conclusions, and elaborations) in their writing. In other studies video modeling has been used to improve spelling. Kinney et al. (2003) developed video models that showed one of the researchers writing a word in response to a prompt from an off-camera investigator. After writing the word, the first investigator said the word. These videos were subsequently used by the classroom teacher to teach new words to the student. The researchers reported that the student readily participated in the instructional sessions, learned a large number of new words, and maintained her knowledge of most of the new words over time. Kagohara et al. (2012) sought to increase the use of the spell-check function of two students with ASD through the use of video modeling. Both of the students successfully learned to use the spell-checker and continued to use the method after the video modeling intervention was discontinued.

Future Directions

Studies of writing interventions have clearly established that individuals with ASD can benefit from such instruction. This is true for both those individuals with lower measured cognitive functioning and those with IQ scores in the average to

higher range. A number of different instructional practices have been found to improve specific writing skills although the most effective approaches often use a combination of methods including self-regulation, strategy instruction, graphic organizers, reinforcement, prompting, and technology. Future research should focus on which of these methods is most useful for the improvement of specific skills (e.g., spelling, written expression, planning) and for which subset of individuals with ASD (e.g., those with lower measured cognitive ability or those higher cognitive functioning).

Additionally, the effectiveness of technology to enhance writing skills has only begun to be explored. The proliferation of technology, in particular speech recognition software and text-to-speech software, has yet to be examined as potential methods for enhancing the written language skills of individuals with ASD. When combined with some of the other evidence-based practices for improving writing skills, the impact of both technology and these practices can potentially be multiplied. The future of research and practice in enhancing the written language skills of individuals with ASD is very promising. The research demonstrates that writing skills can be successfully taught and that individuals with ASD can potentially be more successful both in school and in post-secondary education as well as in employment.

Written communication

Definition

Written language is the written form of communication which includes both reading and writing. Although written language may at first be considered to simply be oral language in its written form, the two are quite different in that oral language rules are innate whereas written language is acquired through explicit education.

Written language, whether reading or writing, requires basic language abilities. These include phonological processing (understanding that words are made of discrete sounds, then associating letters with these sounds, i.e., decoding), vocabulary, and syntax (grammar). Skilled reading and writing further require an awareness of what is being read or written in order to construct meaning. Given characteristic and varying

difficulties in language in individuals with autism spectrum disorders (ASD), the bidirectional relationship between oral and written language poses challenges to written language development.

Further, although reading and writing are based upon the same basic language skills, they are differing forms of written communication with different levels of cognitive demand; these demands present additional challenges to those with ASD learning to read and write. Specifically, writing is more complex than reading because successful written expression requires adequate executive processes (Hooper 2009), that is, processes for planning, organizing, translating (thoughts into words), revising, and editing. Furthermore, writing puts greater demands on internal working memory than does reading does (Berninger and Winn 2006). Additionally, written expression requires handwriting skills, “pen to paper.”

Definition

Xanax, the brand name of Alprazolam, is a member of the benzodiazepine (BZD) family, a category of drugs commonly prescribed for conditions such as insomnia, anxiety, agitation, muscle spasticity, and epilepsy. Xanax is classified as a high-potency benzodiazepine and is known to have a short-lasting anxiolytic effect, meaning the drug reduces anxiety and has a half-life of

approximately 6–27 h half life; it is consequently often prescribed for panic disorder and anxiety-related disorders, such as generalized anxiety disorder (GAD) and obsessive compulsive disorder (OCD). To treat anxiety, Xanax is most commonly taken by mouth in 0.25–0.5 mg tablets up to three times per day. For panic disorder, it is recommended the drug be taken at a maximum of 6–10 mg per day.

Concerning the mechanism of action, Xanax binds to GABA-A receptors, ion channels that have an affinity towards chloride. When the compound binds at two transected subunits of the complex, it in turn alters the shape of the complex's chloride channels and allows GABA to bind. GABA, a common inhibitory neurotransmitter, is known to interfere with brain activity and the connectivity of brain structures, therapeutically resulting in sedation and relaxation of the body. Furthermore, when Xanax binds to subunits of the GABA-A receptor complex, specific isoforms of those subunits regulate the effects of sedation, antianxiety, hypnosis, and amnesia.

Because of its fast-acting properties, Xanax can provide more immediate relief for individuals with anxiety, compared the use of SSRIs or buspirone. Yet the administration of Xanax may also result in impairments in executive functioning, affecting the patient's alertness, diligence, and decision-making. Because of the drug's high potency and high lipid solubility, the possibility of memory deficits, such as anterograde amnesia and impairments in delayed recall, are risk factors.

Rebound anxiety is also a possible side effect when withdrawing from Xanax, which results in a worse return of the original symptoms. Rebound anxiety is more often to occur with a benzodiazepine like Xanax, because of its shorter elimination half-life compared to other BZDs, such as diazepam. In addition to rebound, the fast-acting, short-lived properties of Xanax also expose the patient to risks of withdrawal symptoms and dependence.

In terms of Xanax and its relation to autism, anxiety-related disorders are a common comorbidity of autism spectrum disorders (ASD). Multiple classes of drugs, such as antidepressants, stimulants, anticonvulsants, and antipsychotics are used by youth with ASD to treat comorbid or related diagnoses. Compared to the above classes, benzodiazepines appear to be less commonly used within the community. It is important to note that while benzodiazepines are sometimes taken to directly treat a related diagnosis such as anxiety disorder or epilepsy, they are not prescribed to treat the core symptoms of ASD.

Additionally, there is some recent evidence that suggests that the GABA system may be involved with the pathophysiology of ASD. Several mouse models have shown a reduction in GABAergic interneurons, thus maintaining an imbalance of excitation and inhibition in the brain. This imbalance is thought to be associated with the characteristics of the autism phenotype.

X-Linked Traits

Paul El-Fishawy
State Laboratory, Child Study Center, Yale
University, New Haven, CT, USA

Definition

The traits of an organism are its characteristics. These can be normal characteristics such as stature and eye color or abnormal or disease characteristics, such as blindness or the symptoms of autism. Traits are influenced by two main factors – the environment and an organism's genetic material, the biological instructions for the development and functioning of a living organism.

These instructions are contained in a molecule called deoxyribonucleic acid (DNA). The instructions are spelled out in a sequence or code of four chemical units called nucleobases (or bases). This molecule is contained within nearly every cell of an organism, cells being the building blocks of organisms. Certain segments of the DNA

molecule called genes contain the code for creating the components of cells, most importantly, molecules called proteins.

DNA is passed from one generation to the next. In humans, the DNA is not comprised of a single long molecule but rather is divided up into a set of smaller pieces that correspond to structures called chromosomes, which contain both a single long DNA molecule and proteins. By definition, cells of males contain a chromosome X and a chromosome Y while cells of females contain two of chromosome X. The X and Y chromosomes are referred to as the sex chromosomes. Each parent passes one of his or her sex chromosomes to each offspring. By definition, male offspring can inherit their X chromosome only from their mothers (as the father's Y chromosome is necessary for the creation of male offspring), while female offspring inherit one X chromosome from each parent.

Sex chromosomes stand in contrast to the other human chromosomes that are called autosomes. Autosomes are paired in an individual so that each carries two of chromosome 1, for example. One member of the pair is inherited from the individual's father and the other from the mother.

Traits that result from the sequence of DNA on the X chromosome are called X-linked traits. Rare variations in the DNA sequence are sometimes called mutations. When mutations in the genes on the X chromosome lead to disease, the disease itself is referred to as an X-linked disease. Color blindness is an example of such a disease. Fragile X syndrome, an intellectual disability syndrome that is associated with an increased risk for autism, is another example of an X-linked disease.

In autosomes, mutations in a gene on a single chromosome of a pair can lead to a disease or contribute to disease risk. In the most dramatic case in which a single variation or mutation present on only one of the two chromosomes in a pair leads to a phenotype, this is called a dominant mutation. However, in some cases, a mutation in a gene on one chromosome of a pair will not be sufficient to result in disease because a non-mutated copy of the gene that exists on the other chromosome compensates. Only when mutations in the gene occur on both chromosomes in a pair will the disease occur. These are called recessive

mutations. In autosomes, these rules by and large do not vary on the basis of the sex of an individual.

X-linked mutations can be dominant and recessive as well. However, since not all the genes on chromosome X are represented on chromosome Y, the inheritance pattern of X-linked dominant and recessive mutations differs from that of analogous mutations on autosomes.

In males, an X-linked recessive disease mutation will result in disease because there is not an additional nonmutated X chromosome to compensate. In females, however, such a mutation would only result in disease if the other chromosome X also had a disease mutation in the gene in question. If the gene on only one of a female's X chromosomes was mutated, then the non-mutated X chromosome would compensate, and the individual female would not be affected by the disease. Such females would be called "carriers" of the disease since they carry a disease gene but do not manifest the disease.

In X-linked recessive disorders, a common pattern of inheritance within families, therefore, is as follows. The disease is seen to be passed from apparently healthy mothers who are carriers to their sons but not to their daughters.

In X-linked dominant diseases, a mutation on only one copy of chromosome X is sufficient to result in disease. Thus, even females with one mutated X chromosome and one nonmutated one will have the disease.

The inheritance pattern commonly seen in X-linked dominant disorders depends on which parent carries the mutated chromosome X. If of the parents, only the father has the mutated chromosome, he will pass the disease to all of his daughters and none of his sons since he passes only chromosome Y to his sons. If of the parents, only the mother has the mutated chromosome, she will pass the disease in equal proportion to daughters and sons.

It is important to note that this nomenclature evolved in reference to so-called Mendelian inheritance. These are cases in which there is a highly reliable relationship between the presence of a dominant, recessive, or X-linked mutation and the presence of a disorder or disease. Autism is thought, in contrast, to be a complex genetic disorder in which many different variations do not

cause but rather contribute to the risk for the emergence of the phenotype. These variations, while not as predictive as those found in Mendelian disorders, may also show dominant, recessive, or X-linked effects. As noted, there are also examples of genetic syndromes, such as Fragile X, that are associated with an increased rate of ASD. Finally, there have also been rare cases of genes contributing to “nonsyndromic” autism showing Mendelian inheritance, including X-linked inheritance.

Definition

Yale Global Tic Severity Scale: The YGTSS is a commonly used measure to document the severity of motor and phonic tics. It is performed by a clinician interview. The clinician reviews a list of possible tics that may have occurred over the past week, first motor and then vocal tics. Once the tics that have occurred over the past week are established, the interviewer goes on to ask about the frequency of the tics, the intensity or forcefulness of the tics, the complexity of the tics, and the extent to which the tics are directly interfering in the person's daily life. These dimensions are rated for both motor and phonic tics. The combined total is often used as a measure for overall tic

severity. The YGTSS also includes an overall impairment scale rated from 0 to 50. A score of 0 would indicate that the presence of Tourette syndrome has no negative impact on a person's life. By contrast, a score of 50 would indicate marked interference and disability associated with the presence of Tourette syndrome. The overall impairment caused by Tourette syndrome may not be completely driven by the tic severity. Some individuals with mild tics may be deeply troubled and embarrassed by the tics. By contrast, some individuals with marked tics seem to proceed with life without too much difficulty.

Yale In Vivo Pragmatic Protocol

YiPP

Description

The Yale in vivo Pragmatic Protocol is an assessment tool that measures pragmatic language through a semi-structured conversational task in verbal children aged 9–17. It contains a series of predetermined probes to collect information on a variety of conversational speech acts. Within this 30–40-min conversation, the examiner inserts 23 pragmatic probes within five conversational domains (discourse management, communicative function, conversational repair, presupposition, register variation). If the child produces a pragmatic language behavior in response to the probe, the conversation continues and the next probe is administered. If the child does not respond to the probe, the examiner systematically provides a series of prompts to determine whether or not these prompts are helpful in the production of the pragmatic behavior.

Historical Background

The YiPP was developed by Dr. Rhea Paul and piloted at the Yale Child Study Center.

Psychometric Data

This measure is not standardized but yields qualitative information on pragmatic language skills. Norm-reference to a group of typically developing age-mates is provided.

Clinical Uses

This assessment provides a naturalistic means to assess pragmatic language difficulties commonly seen in children with autism spectrum disorders. Due to the probes used in this assessment, it requires the child to speak in full sentences. Thus, this evaluation is best suited for higher functioning children on the autism spectrum. It yields qualitative information in five domains of pragmatic language. The information derived from this tool can be useful for intervention programming.

Various types of yeast can cause infection in different parts of the body. The most common cause

of yeast infection is *Candida albicans*. It can be oral thrush or with vaginitis. Males can also exhibit genital infection. At times, yeast infection can be systemic and potentially very serious (usually this occurs when the individual has some other condition that compromises the immune system, e.g., AIDS). On the skin surface or oral mucosa, yeast infection causes inflammation. Yeast is diagnosed based on microscopic examination and search for characteristic yeast organisms. A range of antifungal drugs is used to treat yeast infection. These can be topical or systemic.

In addition to the medically accepted yeast infections (noted above), others have proposed that “subclinical” yeast infection can cause a wide range of problems and can be treated by a special diet. The notion behind this diet is that yeast infection, sometimes acquired at the time of vaginal birth, causes autism. The diet consists of having children avoid food that contains yeast or fermented foods, perhaps combined with medications used in treatment of yeast infections. Although dramatic claims have been made, the treatment is unproven. (Smith et al. 2014).

Clearly systematic data on this intervention cannot be regarded as having a solid evidence base. Despite this many parents wish to pursue this (or other complementary/alternative) treatment options. Typically dietary interventions focused on yeast advise parents to avoid foods for the child that contain yeast (baked goods) or which are fermented (soy sauce) or aged (cheeses). Sugar is also to be avoided. Occasionally parents will wish to pursue long-term anti-fungal treatments – again with no clear evidence of yeast infection. As noted above, although dramatic claims have been made for these treatments, substantive scientific data are lacking, and the hypothesis of “yeast overgrowth” in children with autism has no scientific basis. Helping parents make informed treatment decisions is an important aspect of medical care in autism.

Definition

The Z score (or standard score) is a standardized way to convert raw scores into values expressed in terms of standard deviation units. It is calculated by taking a raw score and subtracting the mean score, then dividing the result by the standard deviation. (The mean score and standard deviation used in the calculation are specific to the population or test from which the raw score is obtained).

$$Z = (\text{raw score} - \text{meanscore}) / \text{standarddeviation}$$

A Z score of 1.0 indicates that the raw score was 1 standard deviation above the mean. A Z score of -1.0 indicates that the raw score was 1 standard deviation below the mean.

Definition

In recent years, large-scale human genetics studies have led to considerable advances in our

understanding of the biology of autism spectrum disorders (ASD). In particular, these studies have resulted in the identification of a growing list of ASD risk genes that are beginning to converge on common biological mechanisms (De Rubeis et al. 2014; Iossifov et al. 2014; Sanders et al. 2015). At the same time, scientists now face the challenge of leveraging these genetic findings to elucidate the neural circuit mechanisms underlying ASD and to identify novel pharmacotherapies that selectively target these mechanisms. Here, scientists have utilized model systems to advance from risk gene discovery to the elucidation of basic neurobiological mechanisms. These systems include mouse “knockout” models, in which the function of a particular risk gene is disrupted, as well as human induced pluripotent stem cells (iPSCs), which are generated from the cells of an affected individual carrying a mutation in a specific risk gene. More recently, there is growing interest in the use of zebrafish as a system for the functional analysis of risk genes in ASD. There are several unique features of the zebrafish that make it an optimal system for this purpose. First, zebrafish embryos undergo rapid external development and are optically transparent, allowing for direct visualization of basic processes of vertebrate brain development at early stages. Second, zebrafish have large progenies and their larvae are small and highly tractable in the laboratory. These features facilitate their use in high-throughput pharmacological screens, which are not possible in rodents, given their greater size and complexity. Third, zebrafish provide an in vivo system for investigating the effect of risk gene disruption on the neural circuitry underlying simple, quantifiable behaviors, which is a notable limitation of in vitro methods, including human iPSCs. Finally, recent advances in technologies that allow scientists to target genes of interest in zebrafish, together with the inherent ease of genetic manipulation in this system, have contributed to its growing popularity as a tool for the functional analysis of ASD risk genes. As the list of genes that are strongly associated with ASD continues to grow, zebrafish are likely to emerge as a key player in the identification of convergent

biological pathways involving multiple genes and the discovery of novel pharmacological candidates for further investigation in ASD.

Historical Background

Until recently, the major limitation of the use of zebrafish for the functional analysis of risk genes in ASD and other neurodevelopmental disorders was the lack of efficient methods for selectively disrupting a gene of interest. While mouse “knockouts” were generated by isolating stem cells, such an approach was not feasible in zebrafish due to their rapid embryonic development. Indeed, it was only within the past 10 years that the technology for generating zebrafish lacking the function of a specific risk gene became widely available. For this reason, early studies of zebrafish primarily relied on *forward genetics* approaches (Granato and Nusslein-Volhard 1996), in which scientists search for an unidentified gene that when disrupted leads to an observed structural or behavioral phenotype. In particular, a large-scale screen in the mid-1990s was a tour de force that established zebrafish as a valuable system for studying basic mechanisms in genetics and developmental biology. This series of studies, in which zebrafish carrying randomly induced mutations were assessed for a range of morphological and behavioral phenotypes, led to the discovery of hundreds of genes involved in fundamental processes of vertebrate development, including axon pathfinding and locomotion (Baier et al. 1996; Granato et al. 1996; Karlstrom et al. 1996). However, the ability to target a gene associated with a human disorder in zebrafish remained limited. For example, early *reverse genetics* approaches in zebrafish, such as TILLING (Targeted Induced Local Lesions in Genomes), required screening thousands of zebrafish carrying chemically induced mutations to identify a deleterious mutation in a gene of interest (Moens et al. 2008). Another approach to study gene function in zebrafish that is relatively simple to perform in the laboratory is the use of *morpholinos*, which are sequences of nucleotides

that are introduced into zebrafish embryos and transiently reduce the expression of a gene of interest during early developmental stages. While this “knockdown” approach has contributed insights into the role of genes in basic developmental processes, drawbacks include its potential for inducing off-target effects and non-specific phenotypes (Kok et al. 2015). For this reason, scientists have argued that it is important to examine the developmental effects of gene disruption in zebrafish carrying deleterious, heritable mutations in a gene of interest in conjunction with phenotypes resulting from morpholino-induced gene “knockdown” (Kok et al. 2015).

In the late 2000s, the introduction of targeted nuclease technology transformed reverse genetics studies in zebrafish, enabling researchers to selectively induce heritable mutations in a gene of interest (Doyon et al. 2008; Meng et al. 2008). This technology expanded the range of experimental possibilities in zebrafish, allowing researchers to capitalize fully on the advantages of this system for the functional analysis of genes associated with human disorders, including ASD and other neurodevelopmental disorders. Zinc finger nucleases, which are chimeric fusion proteins designed to bind to a gene of interest and disrupt the gene at the target site, were the first available tools. However, this approach was cost-prohibitive and, in some cases, characterized by low efficiencies. More recently, the advent of *CRISPR (clustered regularly interspaced short palindromic repeats)/Cas9* technology, which hijacks an adaptive immune mechanism used by bacteria for protection against viruses to allow scientists to target genes of interest (Jinek et al. 2012), has revolutionized gene editing in zebrafish as well as other model systems. Compared to earlier gene targeting methods in zebrafish, CRISPR/Cas9 offers superior flexibility and efficiency (Hwang et al. 2013). Given these advantages, along with their reasonable cost, this method has allowed scientists to harness the full potential of zebrafish for the functional analysis of ASD risk genes, which has the potential in the next several years to lead to important insights into the biology of ASD.

Current Knowledge

Despite the obvious evolutionary distance between zebrafish and humans, it is important to observe that there is a reasonable degree of conservation between the two systems at the genetic, molecular, and pharmacological levels. First, zebrafish are vertebrates and share the same major brain subdivisions as humans, including the forebrain, midbrain, hindbrain, and spinal cord (Guo 2009). Neurotransmitter systems and neural cell types are also largely conserved. Second, there is evidence for conservation of pharmacological pathways in zebrafish and other vertebrates, based on similarities in their behavioral responses to psychoactive agents (Guo 2009; Rihel et al. 2010). Third, there is conservation at the genomic level, such that over 80% of genes associated with human disorders have an orthologous gene in zebrafish (McCammon and Sive 2015). Given the advantages of the zebrafish system, as discussed above, zebrafish represent a reasonable “balance” between experimental manipulability on the one hand and conservation on the other (McCammon and Sive 2015). Taken together, the relative conservation of zebrafish at the level of central nervous system structure, genetics, and pharmacological pathways provides support for its use as a translational tool for investigating the function of genes that are strongly associated with ASD in basic neurodevelopmental processes (Ijaz and Hoffman 2016).

At the same time, there are limits to translating findings from zebrafish or any animal system to human disorders. First, there are notable anatomical differences between zebrafish and human brains, including the lack of a neocortex, which is present in mice and clearly limits the translation of findings from zebrafish to humans (Guo 2009; McCammon and Sive 2015). Second, there is less conservation between genes in zebrafish compared to mammalian systems, which may complicate the ability to identify the orthologs of human genes in zebrafish (McCammon and Sive 2015). Third, it is impossible for any animal system to recapitulate the complex range of clinical features in ASD or any neuropsychiatric disorder. For this

reason, it is important to emphasize that the goal of studying zebrafish is to leverage the unique advantages of this relatively simple system to analyze the function of ASD risk genes in basic neurodevelopmental processes.

A number of studies have capitalized on the advantages of zebrafish to investigate the role of ASD risk genes in nervous system development, with many of these studies employing a morpholino-based approach, as described above, to reduce the expression of genes of interest. For example, Kozol et al. (2015) knocked down two ASD-associated genes, *SYNGAP1* (*Synaptic Ras GTPase Activating Protein 1*) and *SHANK3* (*SH3 and Multiple Ankyrin Repeat Domains 3*), in zebrafish, and found that reduced expression was associated with abnormal swimming and escape behaviors, as well as developmental delay and microcephaly. In addition, Blaker-Lee et al. (2012) studied the effect in zebrafish embryos of reducing the expression of 22 genes found in the region of human 16p11.2. Copy number variants in this region are strongly associated with ASD and other neuropsychiatric disorders, including schizophrenia and intellectual disability, yet the contribution of individual genes in the region to ASD is poorly understood. By performing a series of morphological and behavioral assays, the authors found that the reduced expression of many of these genes led to brain and behavioral abnormalities, such as decreased brain ventricle size, abnormal midbrain structure, or alterations in spontaneous movement and touch response (Blaker-Lee et al. 2012). Another zebrafish study found that reduced expression and overexpression of one of the genes in this region led to macrocephaly and microcephaly, respectively, suggesting dose-dependent effects (Golzio et al. 2012). At the same time, it is important to observe that morpholinos are limited by their potential for inducing off-target effects, such that there is growing emphasis on confirming phenotypes resulting from gene knockdown in mutants, where gene function is permanently disrupted (Kok et al. 2015). With the advent of CRISPR/Cas9 technology, this goal is becoming increasingly feasible.

Recent studies have also capitalized on the large progenies of zebrafish and the small size of their embryos and larvae to develop quantitative simple behavioral assays for conducting high-throughput pharmacological screens. For example, Rihel et al. (2010) tracked the locomotor activity of zebrafish larvae automatically on a light-dark cycle in response to hundreds of psychoactive compounds to analyze the effects of these drugs on their rest-wake cycle behaviors. Intriguingly, this study demonstrated that psychoactive compounds could be correctly classified by their mechanism of action based solely on the readout of their behavioral effects in zebrafish larvae. In addition, Kokel et al. (2010) screened thousands of compounds for their effects on the photomotor response, a characteristic motor response exhibited by zebrafish embryos following exposure to a light stimulus, and found that their behavioral responses could be used to correctly categorize novel psychotropic compounds. These studies reveal the potential of large-scale screens of simple behavioral responses in zebrafish to uncover pharmacological mechanisms. In a recent study, Hoffman et al. (2016) utilized this automated behavioral profiling approach to analyze the locomotor activity of zebrafish carrying deleterious mutations in the ASD risk gene, *CNTNAP2* (*Contactin Associated Protein-like 2*). This study found that these zebrafish mutants displayed deficits in inhibitory neurons, had increased sensitivity to drug-induced seizures, and were hyperactive at night. By comparing the abnormal behavioral profile of mutants to the known effects of over 500 compounds in control fish (Rihel et al. 2010), this study found that estrogenic compounds, including the plant-derived estrogen, biochanin A, were able to selectively rescue the abnormal behavioral phenotype in mutants, identifying a novel pharmacological pathway not previously associated with *CNTNAP2* (Hoffman et al. 2016). In another study, Baraban et al. (2013) conducted a large-scale drug screen to identify compounds that suppress spontaneous seizure-like behaviors in zebrafish carrying a loss-of-function mutation in a gene that is closely related to *SCN1A* (*Sodium Voltage-Gated Channel Alpha Subunit 1*), which is associated with a rare

syndrome of intractable epilepsy called Dravet syndrome. Of the 320 compounds tested, the authors identified a single compound, clemizole, which could reverse abnormal seizure-associated behaviors and electrophysiological abnormalities in mutants (Baraban et al. 2013). These studies highlight the potential of the zebrafish system as a *first-pass screening approach* to identify novel pharmacological candidates with relevance to ASD and other neurodevelopmental disorders for further investigation in mammalian systems.

Future Directions

There are a number of emerging technologies that are likely in the next several years to expand the repertoire of questions that scientists can address using the zebrafish system. First, genetically encoded fluorescent calcium indicators are allowing scientists to image the activity of individual cells throughout the brain of a live larval zebrafish at high resolution, which is possible given their transparent heads. These live imaging assays are increasingly being used to study the neural circuitry underlying simple behavioral tasks, such as the optomotor response and prey capture (Filosa et al. 2016; Muto et al. 2013; Portugues et al. 2015). By visualizing brain activity in zebrafish lacking the function of ASD risk genes, scientists can begin to explore how the disruption of these genes leads to abnormalities in specific neural circuits. Second, the advent of CRISPR/Cas9 gene-editing technologies is facilitating the targeting of multiple ASD risk genes in zebrafish, providing scientists with the opportunity to leverage this approach to investigate the effect of multiple ASD risk genes on brain development simultaneously. Third, high-throughput, automated pharmacological screens based on simple larval behaviors, as described above, have the potential to serve as an important first-pass screening tool to uncover neurochemical pathways that are disrupted due to loss of ASD risk genes and novel pharmacological candidates for further evaluation in mammalian systems. Therefore, the zebrafish system holds considerable translational promise, in conjunction with mouse and cell

culture models, to advance our understanding of neurobiological mechanisms in ASD. Taken together, given the unique features of this system, the zebrafish has the potential to emerge as a key contributor to the functional analysis of ASD risk genes and the elucidation of convergent biological and pharmacological mechanisms in ASD.

Definition

The term *zero reject* refers to the requirement that an individual with a disability recognized by the Individuals with Disabilities Education Act (IDEA) cannot be denied access to special education and necessary related services in the United States. This explicitly implies that a local education agency (LEA) must make an affirmative effort to determine eligibility for special education

services, develop a free and appropriate individualized educational plan, implement that plan in the least restrictive environment, and demonstrate that the plan is effectively addressing the educational needs of a student with a disability. The LEA does not have the right to refuse (reject) determination of need, or provision of services, under federal law.

Ziprasidone is atypical antipsychotic medication that has been on the marketplace since early in the 2000s. It is distinguished from others of the class in that it appears to be less likely to cause weight

gain. There are a few studies that have examined the benefits of ziprasidone in children or adults with autism, so information on dose and effectiveness is incomplete. Although rare, a drawback of ziprasidone is that it has a potential for affecting electrical signals in the heart. Most clinicians do not consider it as a first-line treatment because of this concern.

Despite its high prevalence, few pharmacological treatments outside antihistamines and melatonin exist for sleep disorders among pediatric populations (Chevreuil et al. 2010). Few clinical trials have examined whether benzodiazepines, such as Zolpidem, may benefit autistic spectrum disorder (ASD) children with sleep disorders (Chevreuil et al. 2010). A recent case report suggests Zolpidem was effective in reducing catatonic behavior in an adolescent with ASD (Zaw and Bates 1997). However, murine models suggest zolpidem exacerbates social and cognitive deficits observed in ASD children (Banerjee et al. 2012; Han et al. 2014). Further clinical trials are required to elucidate the mechanism, therapeutic use, and side effects of Zolpidem among ASD children with sleep disorders.

Zone of Proximal Development (ZPD)

Definition

A concept developed by the Russian psychologist Lev Vygotsky (1896–1934) to describe the point where a child (or adult) is most able to learn, i.e., just past the point at which a skill/task/activity has been mastered but not so difficult as to be impossible for the child to learn. From the educator's point of view, this suggests giving the child materials/tasks that are carefully selected to enable the child to advance without overwhelming them. Put another way, this notion refers to tasks that the child is capable of learning and performing (often initially with guidance) before these become fully independent activities. High interest in the topic was based on his awareness that for most children certain activities (e.g., language learning) were more effortless than work in other areas (e.g., mathematics). His work also reflected an awareness of distinguishing between development and teaching and has implications for theories like those of Jean Piaget on cognitive development. In Vygotsky's view, a middle ground was needed between self-directed learning and explicit educational instruction. For him a good teacher was one who directed teaching at the child's specific level of ability. His death at a young age meant that he did not fully develop the concept.

The concept of the zone of proximal development prefigures in important ways certain current approaches to treatment and intervention (e.g., in learning difficulties). Other approaches, e.g., Maria Montessori's teaching methods, similarly attempt to match activities with skills that are emerging for the individual child. Other theorists have referred to these concepts in slightly different ways, e.g., J. McV. Hunt (1961) referred to the "problem of the match," that is of being aware of exactly where the child was developmentally and providing a slightly more challenging task. The notion has also been viewed as an important aspect of scaffolding helping the child learn from peers as well as teachers. In this process, the teacher or a knowledgeable peer help a student who is just at his or her zone of proximal development to learning a more challenging task. Clearly an awareness of where the child is actually at is critical in this regard. The concept has been extensively used in educational settings. It has implications not only for teacher-directed learning but the assistance of peers as well.

The social context of children's learning is important given the usual indication of the child to learn by imitation, and this imitation and ability to learn socially provides an important tool for learning. Thus by teaching children at a level slightly above current skill levels, parents and teachers help them expand their abilities. The concept applies not only to more straightforward school-related tasks but other complex activities, e.g., riding a bicycle, learning to drive a car. It is important for parents and teachers to avoid teaching outside the zone of proximal development; conversely, it is also important that parents/teachers are able to sensibly withdraw scaffolding when a child has mastered, or is well on his or her way to mastering, an activity. The use of older peers/mentors can be important in helping the child learning a slightly more challenging task.

For individuals with autism spectrum disorders, an awareness of the child's levels of functioning in specific areas is critical given that some skills (e.g., nonverbal tasks like puzzles) are learned with greater ease than other (e.g.,

language-based) tasks. As with typically developing children, teachers and peers can be helpful in facilitating learning in the child with ASD as tasks are "pitched" superficially at an appropriate level and within the ability of the child with ASD to learn.

Definition

It describes DNA sequence similarity or origin at a particular genetic locus or between twins. In diploid organisms, where one allele is usually inherited from the mother and one from the father, zygosity describes whether these homologous alleles have identical (*homozygous*) or different (*heterozygous*) DNA sequence. A diploid individual may also be missing one (*hemizygous*) or both (*nullizygous*) alleles. Alleles are *autozygous* if they originate from a common ancestor via nonrandom mating or inbreeding; *autozygous* alleles are homozygous. Alternatively, alleles that coincide via random mating are *allozygous* and may be homozygous or heterozygous. Twins are described as *monozygotic* (MZ) when a single egg is fertilized to form one zygote, which later divides into two embryos. *Dizygotic* (DZ) twins occur when two eggs are fertilized independently, yielding two zygotes; on average, they share 50% of their DNA sequence, similar to nontwin siblings. Comparisons of concordance (shared diagnosis) rates between MZ and DZ twin pairs are used to establish the overall heritability of conditions or phenotypes in “twin studies.” Multiple twin studies have been conducted in autism spectrum disorders and demonstrate a significant role for genetic factors in the etiology of these syndromes.

Definition

Despite advancements in cognitive-behavior therapies, no single pharmacological therapy has successfully treated the disruptive-compulsive behaviors of Autism Spectrum Disorders (ASD), which include hand-flapping, tantrums, and self-injurious behaviors (Fido and Al-Saad 2008). Among the pharmacological agents examined to reduce disruptive-compulsive behaviors, atypical antipsychotics, including olanzapine, showed the most promise (Fido and Al-Saad 2008; Malek-Ahmadi and Simonds 1998; Malone et al. 2001). Specifically, ASD children prescribed olanzapine showed significant reductions in irritability, hyperactivity, and lethargy (Fido and Al-Saad 2008; Malek-Ahmadi and Simonds 1998; Malone et al. 2001). Unlike typical antipsychotic medications, atypical antipsychotic medications block postsynaptic dopamine and serotonin receptors and have a lower risk of extrapyramidal symptoms, such as dyskinesias, among children and adolescents (Malone et al. 2001). However, patients prescribed olanzapine experience several side-effects including: hyperlipidemia, hyperprolactinemia, weight gain, and tardive dyskinesia (Fido and Al-Saad 2008). Other case reports have also reported hyponatremia and excessive masturbation from prolonged use of olanzapine among ASD patients (Chiang et al. 2013; Hergüner 2010). In addition, it remains uncertain whether long-term use of olanzapine produces detrimental effect to learning and development of ASD children (Fido and Al-Saad 2008). Further studies of olanzapine are required to

determine its long-term side-effects and potential applications for treating symptoms of ASD.
